Figure 1 displays the general design of a decision support system for the Graph Model for Conflict Resolution, which is referred to as GMCR II, [12,13]. As can be seen, via the user interface, an analyst can interact with the modeling subsystem, analysis engine, and output interpretation subsystem when investigating a given dispute. Within the modeling subsystem, a conflict model is developed in terms of DMs and the options or courses of action available to each DM. On the basis of the combination of ways in which DMs can separately select their options, GMCR II can automatically generate the states or scenarios that could occur. States that cannot possibly take place in reality are removed from the conflict model in order to end up with the list of feasible states. Finally, a very important step is to obtain the relative preferences of each DM with respect to the set of feasible states. In the realm of physical systems, the basic laws of nature, such as gravity, dictate how a particular system will dynamically change. In the social realm of conflict resolution, the value systems of DMs as expressed by their preferences over states are the driving forces of human behavior. Hence, ascertaining the preferences of DMs is a crucial step in the calibration of a conflict model.

After determining an initial conflict model for the dispute under study, the user can instruct the analysis engine to carry out a stability analysis and thereby ascertain the possible equilibria or compromise resolutions to the conflict, which will then appear as part of the output. A given state is deemed to be stable for a particular DM if it is not advantageous for the DM to move to another state. For example, a DM may have the ability to move on his or her own to a more preferred state by changing his or her option selection or strategy. However, if the competitors can invoke countermoves that put the original DM in a less preferred situation, he or she is better off to stay at the initial state which is said to be stable. Because DMs may behave differently in conflict situations, a range of stability definitions have been formulated to define different patterns of moves and countermoves under which these stabilities can take place.

A general approach to follow when executing a conflict study is to first determine how well a given DM can perform on his or her own via independent behavior. Subsequently, one can find out if the DM can do even better by cooperating with others by joining a coalition, in which all members of the coalition benefit when certain actions are taken [14,15].

As indicated in the output interpretation subsystem box in Fig. 1, one can also examine the dynamic evolution of a conflict over time from a given starting state to an attractive equilibrium. In some cases, it may not be possible to reach a desirable situation unless one cooperates with others. In fact, one can use a decision support system in an iterative manner. As one gains a better understanding of the conflict via, for instance, executing basic analyses and discussing these results with others, one can make meaningful changes to the conflict in the modeling subsystem, and subsequently execute another analysis. Further types of investigations that could be carried out are discussed in the section titled "Further Investigations and Insights."

The general Graph Model methodology depicted in Fig. 1 can be used in the following three main types of situations:

- *Analysis and Simulation Tool for a DM in a Conflict, or a DM's Agent.* Moves and countermoves following a DM's possible actions can be analyzed, and the potential consequences of certain actions assessed, in order to improve the DM's position. Preparations and assessments can be carried out at different times as the conflict unfolds. For example, an analyst may advise the US government about strategic initiatives to invoke in Afghanistan over time.
- *Communication and Analysis Tool in Mediation.* GMCR II can be utilized by a mediator to assess possible strategic consequences of a range of preferences for DMs, without knowing which preferences are correct. Options that are beneficial, detrimental, or irrelevant to all parties can be ascertained by using this process. In negotiations

between labor and management over designing a new contract, a mediator may be able to demonstrate how only small concessions and minimum shifts in preferences by each side may result in a mutually beneficial contract.

- *Analysis Tool for a Third Party Analyst.* On the basis of the observed outcome and evolution of a conflict, an analyst can estimate the DMs' preferences. How the structure of the conflict influenced DMs' behavior can also be studied, and better ways to structure a future conflict can be identified. For instance, the government of China may wish to know the strategic effectiveness of US policy in Afghanistan, even though China is not a combatant in Afghanistan.

STRATEGIC STUDY OF THE ARAL SEA CONFLICT

Conflict arising over the ongoing environmental damage caused by societal activities is becoming more widespread and serious. For example, the failure of the nations of the world to reach an effective agreement over the containment and significant reduction of greenhouse gases in Copenhagen in December 2009 means that the consequences of climate change will become much worse, and the ensuing conflict will intensify. Clearly, powerful negotiation procedures and tools are needed now to guide society in a responsible direction. In the past, smaller societies such as those in Easter Island, Greenland, and elsewhere have collapsed largely because of the destruction of the local environment, such as cutting down all of the trees in Easter Island. One of the most dramatic environmental nightmares of the twentieth century was the ecological destruction of the Aral Sea, which was directly brought about by human folly. The purpose of this section is to outline how the Graph Model for Conflict Resolution can be conveniently applied to real-world conflict to gain strategic insights by using it to study a current water quantity conflict existing within the Aral Sea Basin.

Background to the Aral Sea Dispute

Figure 2 displays the Aral Sea Basin, which is located in the heart of the Eurasian continent, where it extends over the territories of the five Central Asian Republics: Kazakhstan, Kyrgyzstan, Tajikistan, Turkmenistan, and Uzbekistan. Some smaller parts of the basin lie in Afghanistan, China, and Iran. As depicted on the map, the two main rivers flowing into the Aral Sea are the Amu Darya, which starts in the mountains of Afghanistan and Tajikistan and flows through Turkmenistan and Uzbekistan to the Aral Sea, and the Syr Darya, which originates in Kyrgyzstan and flows through Tajikistan, Uzbekistan, and Kazakhstan to the Aral Sea [16].

To obtain hard currency through exports, the Soviet Union promoted the large-scale growing of irrigated cotton in the Aral Sea Basin and became a net exporter of cotton in 1937. Beginning in 1960, large quantities of water from the rivers were diverted for irrigating millions of hectares of land, resulting in the level of the Aral Sea beginning to drop. While the sea had been receiving about 50 km^3 of water per year in 1965, by the early 1980s this amount had decreased

to zero. The shrinking of the Aral Sea caused the salinity to increase in combination with a significant decline in the previously large fish catch. Additionally, the declining sea level lowered the water table in the region, which destroyed many oases near its shores, and created dangerous levels of polluted airborne sediments in areas that became dry.

The diversion of water to irrigate agricultural land had other direct negative effects. In particular, ecologically sensitive areas in the river deltas were converted to cropland, pesticides were heavily used throughout the Aral Sea Basin resulting in heavy contaminant concentrations in the sea, and high salt concentrations built up on the irrigated fields. By the start of the 1990s, the surface area of the Aral Sea had shrunk by nearly half, and the volume was reduced by 80%. Regional climate became more continental, thereby shortening the growing season and causing some farmers to switch from cotton to rice, which required even more diverted water. The exposed area of the former seabed was more than $28,000 \text{ km}^2$ from which winds picked up millions of tons of sediments laced with salts and pesticides, with devastating health consequences for people living in the surrounding regions.

Figure 2. Aral Sea Basin.

Table 1. The Decision Makers and Their Options in the Syr Darya River Water Sharing Conflict

Decision Makers	Options
<i>Downstream</i> Two downstream countries: Uzbekistan and Kazakhstan	1. <i>Less fuel</i> : supply less fuel than specified 2. <i>Pressure</i> : exert political and military pressure 3. <i>Follow agreement</i> : follow the present agreement
<i>Upstream</i> One upstream country: Kyrgyzstan	4. <i>Ignore agreement</i> : generate more hydroenergy in winter than agreed upon 5. <i>Follow agreement</i> : do not release too much water for hydropower generation during winter and release sufficient water for irrigation during summer 6. <i>Revise agreement</i> : revise agreement to meet winter hydropower demand and allow for summer irrigation
<i>ICWC</i> Interstate Commission for Water Coordination	7. <i>Enforce agreement</i> : enforce the present agreement. 8. <i>Revise agreement</i> : revise agreement to try to meet new demands of both upstream and downstream countries.

In 1988, the Soviet Union decreed that cotton growing has to be reduced, expecting the Aral Sea to receive water in gradually increasing amounts. However, the dissolution of the Soviet Union in 1991 ended such central authority, and since then the Aral Sea crisis has been under the control of the five Central Asian independent nations consisting of Kazakhstan, Kyrgyzstan, Tajikistan, Turkmenistan, and Uzbekistan. Unfortunately, water use has increased rapidly and is now at an unsustainable level. Under the Soviets, water and energy resources were exchanged freely across the entire region. Since becoming independent, the five Central Asian states have failed to come up with a viable regional approach to replace the Soviet system of management because of intense competition among them. To help overcome this, in 1992, the five states set up an intergovernmental body called the *Interstate Commission for Water Coordination* (ICWC) to manage water resources in the Aral Sea Basin.

The main type of conflict existing in the Aral Sea Basin is the classic battle between downstream and upstream countries, over which nation controls and utilizes the water in the main rivers flowing across the basin to the Aral Sea. More specifically, the downstream countries require large quantities of water for their expanding agricultural sectors

and rising populations, while the economically weaker upstream countries need more water for electricity generation and farming.

Nandalal and Hipel [17] provide an overview of the recent history of the Aral Sea Basin as well as references in which detailed information and environmental studies of the area can be found [16,18–20]. These authors used the Graph Model for Conflict Resolution to carry out a strategic examination of the downstream versus upstream conflict among countries along the Syr Darya river. The conflict study presented in this section to illustrate how the Graph Model can be used in practice is based on the work of Nandalal and Hipel [17].

Modeling the Aral Sea Dispute

Under the modeling subsystem shown in Fig. 1, one can see that two key components in constructing a conflict model are the DMs and the options or courses of action controlled by each DM. The left column in Table 1 lists the three main DMs in the water sharing conflict along the Syr Darya river as Downstream (Uzbekistan and Kazakhstan), Upstream (Kyrgyzstan), and the ICWC. The right column furnishes the options under the control of each DM along with an explanation as to what each option means.

After modeling and analyzing the conflict following the steps given in the section titled

Table 2. Evolution of the Conflict from the Status Quo, Through Two Transitional States, to the Final Resolution

Decision Makers and Options	Initial State		First Intermediate State		Second Intermediate State		Final Equilibrium
<i>Downstream</i>							
1. Less fuel	N		N		N		N
2. Pressure	Y	→	N		N		N
3. Follow agreement	N	→	Y		Y		Y
<i>Upstream</i>							
4. Ignore agreement	Y		Y	→	N		N
5. Follow agreement	N		N	→	Y		Y
6. Revise agreement	N		N		N		N
<i>ICWC</i>							
7. Enforce agreement	N		N		N		N
8. Revise agreement	N		N		N	→	Y

“Systematic Investigation of Real-World Conflict” and Fig. 1, a type of dynamic insight that one can garner from a formal conflict study is depicted in Table 2. In this table, each column of Y and N stands for a possible state or scenario that could occur in the real-world where a Y means “yes” the option opposite the Y is selected by the DM who controls it, while an N indicates “no” the option is not taken. Hence, the initial state or status quo is the situation whereby Downstream does not supply less fuel, exerts pressure on Upstream not to release excess water in the winter so it is available for irrigating the summer crops downstream, and does not completely follow the agreement. Upstream ignores the agreement and uses more water in the winter, while ICWC does not enforce or revise the agreement. The arrows in Table 2 indicate how option selections change as the conflict evolves over time from the status quo on the left to the two intermediate states shown in the center to the final state or equilibrium given on the right. When moving from the initial state to the first intermediate state, which is more preferred by Downstream to the initial state, Downstream stops exerting pressure (does not take option 2) and follows the agreement (selects option 3). This in turn entices Upstream to adhere to the agreement (choose option 5 instead of 4) to move the conflict from the first intermediate state to the second more preferred intermediate state. Next, the final equilibrium is reached

from the second intermediate state when ICWC revises the agreement and both Downstream and Upstream accept this improved agreement.

Going back to the modeling stage, one must determine the feasible states in the conflict, as indicated in Fig. 1. Since the model in Table 1 contains a total of eight options, each of which can be chosen or not, mathematically there are $2^8 = 256$ possible states. Fortunately, in practical applications, the number of feasible states is much less than the number of mathematically possible states, and for the case of the Syr Darya river water sharing conflict the number of feasible states is only 21. One can easily identify which states cannot occur in this conflict and then remove them using GMCR II. For example, the three options under the control of Upstream are mutually exclusive and, hence, Upstream can only select at most one of its three options which are numbered as options 4, 5, and 6 in Tables 1 and 2. Therefore, if Upstream were to “Ignore agreement” (option 4), its other two options of “Follow agreement” (option 5) and “Revise agreement” (option 6) could not occur, as is the case for the Initial State in Table 2. Likewise, options 7 and 8 are mutually exclusive for ICWC since it only makes sense for this DM to choose at most one of those two options. Any state in which both options 7 and 8 were selected would be removed from the conflict model. For Downstream, the first and third options, and second and third options

Table 3. Solution Concepts and Human Behavior

Solution Concepts	Stability Descriptions
Nash Stability [21,22]	DM (decision maker) cannot unilaterally move to a more preferred state.
General Metarationality (GMR) [3]	All DM's unilateral improvements are sanctioned by subsequent unilateral moves by others.
Symmetric Metarationality (SMR) [3]	All DM's unilateral improvements are still sanctioned even after possible responses by the original DM.
Sequential Stability (SEQ) [4,5]	All DM's unilateral improvements are sanctioned by subsequent unilateral improvements by others.
Limited-Move Stability (L_h) [2,23,24]	All DMs are assumed to act optimally and a maximum number of state transitions (h) is specified.
Nonmyopic Stability (NM) [2,25]	Limiting case of limited-move stability as the maximum number of state transitions increases to infinity.

are mutually exclusive. Moreover, at least one of the three options for Downstream and for Upstream must be taken, since these countries are expected to take action. After removing all the states containing infeasible combinations of option selections that cannot take place, 21 feasible states remain, three of which are displayed in Table 2.

Notice in Table 2 that Downstream can cause the conflict to move from the initial state to the first intermediate state by changing its selection of options, while Upstream can unilaterally move the conflict from the first to the second intermediate state. Likewise, ICWC can make the conflict move from the second intermediate state to the final equilibrium via an option change that it controls. A movement from one state to another is called a *state transitions*; all the state transitions can easily be calculated by GMCR II, given the DMs and options. However, sometimes a transition can take place in only one direction, which is the case for the transition

from the second intermediate state in Table 2 to the final equilibrium. GMCR II can easily keep track of these irreversible moves. Since movement among states can be envisioned as a graph, in which the vertices are the states and the arcs are movements controlled by DMs, the conflict methodology described in the previous section is referred to as the *Graph Model for Conflict Resolution*.

The last, and most important, type of information needed to build a conflict model is the relative preferences of each of the DMs with respect to the states or scenarios that could take place in the conflict. Therefore, one only needs to specify each DM's ordering of the states, with ties allowed; there is no requirement to estimate the amount or intensity of any preference. Accordingly, cardinal preference information, such as utility values, is not required; the user of GMCR II enters only information that permits GMCR II to determine a ranking of states from most to least preferred for each DM, where some states may be equally preferred.

Option prioritization is a clever procedure used within GMCR II to obtain relative preference information for each of the DMs, whereby preferences are stated in terms of prioritized logical statements about which options are selected. Table 3 presents the preference statements in the order of priority for Downstream, from most important at the top of a column to least important at the bottom. The numbers in the left column of Table 3 refer to option numbers, and an English explanation for each preference statement is provided in the right column. Option number 5 located at the top means that Downstream most prefers to see Upstream follow the agreement, as explained on the right. Option number 3, written below 5, indicates that Downstream's next preference is for itself to follow the agreement. In the order of decreasing preference, Downstream would like to supply less fuel or petroleum from its oil reserves (option 1), followed by exert pressure (option 2). After that, Downstream would like Upstream not to ignore the present agreement, as indicated by the negative sign in front of option 4. Next, Downstream does not want Upstream or ICWC to revise the agreement ($-6|-8$,

Table 4. Option Prioritizing for Downstream

Preference Statements	Explanation
5	Downstream most prefers to see Upstream follow the agreement by taking Option 5.
3	Next, Downstream's preference is for itself to follow the agreement (choose Option 3).
1	Downstream would like to supply less fuel (select Option 1).
2	Downstream's next preference is to exert pressure (take Option 2).
-4	Downstream would like Upstream not to ignore the present agreement (as indicated by the negative sign before Option 4).
-6 -8	Downstream does not want to see Upstream or ICWC revise the agreement (not select Option 6 or Option 8, where stands for "or").
7	Downstream would like ICWC to enforce the agreement (take Option 7).

where | means "or". Lastly, Downstream would like ICWC to enforce the agreement (option 7).

Written horizontally in text from most to least important, the preference statements for Upstream are 5, 3, 4, 6|8, 7, -1, -2, while those for ICWC are 3 and 5, 8|6, 7 if 1|2, -4, -1| -2. A major advantage of the option prioritization approach to preference elicitation is that it closely reflects the way in which a person thinks about preferences in a given conflict. In fact, one can readily obtain prioritized preference statements in terms of options for a DM, either directly from the DM or from published descriptions of the conflict as is demonstrated here. From a theoretical viewpoint, these preference statements adhere to all of the rules of first-order logic. Under the assumption of what is called *transitivity of preferences*, GMCR II possesses an algorithm for taking the prioritized preference statements for each DM to produce a ranking of states in which ties are permitted. Frequently, a given DM's most and least preferred preference statements are initially known. When GMCR II ranks

the states based on a limited number of preference statements, there may be blocks of equally preferred states contained within the ordering of states. As more preference information becomes available, these equally preferred blocks will become less prevalent and will fully disappear when there are sufficient preference statements to produce complete ranking of states from most to least preferred with no ties. Nonetheless, even when there are blocks of equally preferred states for one or more DMs, GMCR II can still carry out stability analyses. From a practical viewpoint, this means that one can begin with a "quick and dirty" analysis and later refine preference statements as more information becomes available. In their paper, Nandalal and Hipel [17] show the ranking of states for the three DMs in the Syr Darya water sharing dispute.

Analysis and Results

As shown in Fig. 1, after a conflict model has been constructed, a stability analysis is executed using GMCR II to determine the stability of every state, for every DM, for all of the stability definitions listed in Table 4. These stability definitions describe the patterns of interaction that a DM may expect when dynamically interacting with others in terms of moves and countermoves. If it is not advantageous for a given DM to depart unilaterally from a particular state according to a given stability definition, then the state is deemed to be stable for that DM under that stability definition. For example, under the solution concept of Sequential Stability listed in Table 4, if all of a given DM's unilateral improvements from the state under consideration can be sanctioned by unilateral improvements by others, the particular state is stable according to sequential stability for that DM. If a state is stable according to a given stability definition for all of the DMs, it constitutes an equilibrium under that stability definition, and is, therefore, a compromise resolution, because no DM has an incentive to unilaterally move away from it. Fang *et al.* [2] present mathematical definitions and comparisons in graph model form for the stability definitions provided in Table 4. The original references for these

Table 5. Further Extensions of the Graph Model for Conflict Resolution

Area	Specific Topic	Explanation
Preferences	Strength of preferences	An environmentalist may greatly prefer the situation in which a company is not allowed to seriously pollute the surrounding environment. When possible unilateral improvements by a DM can be blocked by others by putting the DM in a state that is greatly less preferred, this creates a strong type of stability [34,35]. The concept of strength of preference has been generalized to multiple levels of preference [36], which can be interpreted as bringing relative preference information close to the concept of cardinal preferences.
	Unknown preferences	When the relative preference between two states is unknown, this valuable information is taken into account when calculating individual stability and potential resolutions [37]. Hence, this approach is not based upon probability or fuzzy set theory.
	Fuzzy preferences	Allowing preferences to be “fuzzy” is one way to model uncertain preference in which, for example, a DM may more or less prefer one state over another or definitely prefer one state more than the other. Fuzzy preference information can be utilized to determine fuzzy stability [38].
Psychological factors	Attitudes	In a conflict, a given DM can have a positive, neutral or negative attitude toward him or herself and others. One would expect that when all DMs in a dispute possess positive attitudes toward themselves and others a better resolution for everyone concerned can be reached. In practice, this is a common occurrence [39,40].
	Emotions	Emotions often arise in conflict situations and can propel a given dispute toward a range of final outcomes depending upon the mix of emotions that are present. The perceptual graph model is a useful approach to formally incorporating emotions into conflict investigations [41,42]. Emotions can also be expressed via strength of preference, which can be formerly modeled within the Graph Model methodology.
	Hypergames	In a hypergame, one or more DMs have a misunderstanding regarding preferences of others, available options, which DMs are participating in the conflict, or any combination of the foregoing misinterpretations. Hypergame analysis is a way for formally modeling misunderstandings and determining their strategic consequences. Because a conflict may contain misunderstandings, based on other faulty interpretations of reality, hypergames possess multiple levels of perception [43,44].

stability definitions are given in the left column in Table 4.

After carrying out an exhaustive stability analysis using GMCR II, the most likely equilibrium is the one shown on the right in Table 2, in which both Downstream and Upstream agree to follow a revised agreement proposed by ICWC. This is a particularly strong equilibrium since it is an equilibrium according to all of the stability definitions given in Table 4. The pathway for reaching this compromise resolution is indicated by the evolution of the conflict from the initial state on the left via the

intermediate states to the final outcome on the right in Table 2.

FURTHER INVESTIGATIONS AND INSIGHTS

As exemplified by the Aral Sea application in the section titled “Strategic Study of the Aral Sea Conflict,” the Graph Model provides a flexible decision technology for obtaining strategic insights with respect to this complex systems problem. At the start of this article, many of the key capabilities of this systems methodology are listed. For applications of the Graph Model to many different types of disputes in areas such as international trade

and environmental engineering, the reader can refer to Hipel *et al.* [26,27] and Hipel and Obeidi [28] as well as references cited therein.

Subsequent to carrying out a basic study similar to the one just done for the Aral Sea Basin conflict in the previous section, one may wish to execute further investigations to gain a deeper understanding about the conflict and additional strategic insights. Often this type of approach is referred to as a *sensitivity analysis*, in which parameters of a model are changed in a meaningful manner to see how the output is altered. If, for example, changes in the preferences of a given DM do not change the key equilibria, which have already been calculated, these equilibria are robust with respect to these preference changes.

As pointed out in the section titled “Systematic Investigation of Real-World Conflict,” after one ascertains the best that each DM can do on his or her own, one should also determine if DMs can fare even better through cooperation with others by forming coalitions [14,15]. In addition, one can check which equilibria can be reached from a given initial state or status quo through both independent and joint movement [29,30]. Zeng *et al.* [31] explain how the Graph Model can be extended for employment in policy analysis. Table 5 summarizes other expansions of the Graph Model that have been made, some of which are under further development. Finally, the matrix approach for equivalently defining the Graph Model for Conflict Resolution provides the systematic structure for formally incorporating all the foregoing advancements into the Graph Model as well as associated algorithms for designing the next generation of a decision support system [32,33].

THE HUNGARIAN OPERATIONS RESEARCH SOCIETY

TIBOR CSENCES
Department of Computational
Optimization Szeged,
University of Szeged,
Hungary

HISTORY OF THE SOCIETY

The Hungarian Operations Research Society (HORS) was founded in Budapest in 1991, shortly after major political changes in the country. By that time, Operations Research (OR) was already represented in main research and scientific bodies, such as the Operations Research Committee of the Hungarian Academy of Sciences (HAS), the Applied Mathematics Department of the János Bolyai Mathematical Society and the Society of Economic Modeling. Still, the founders felt that it was important to have an independent association for OR. This structure of professional society life exists since that time, and obviously these scientific bodies serve the interest of the OR community quite well. Since decades, our society organizes the biannual Hungarian Operations Research Conference in rotation with the last two. Also, HORS enjoys a fruitful collaboration with all the abovementioned scientific bodies.

The honorary president of HORS is András Prékopa (EURO Gold Medal laureate, Rutgers University and Eötvös Loránd University, Budapest), member of the HAS. Béla Martos (1920–2007) also acted as the honorary president of HORS. Three honorary members were elected: Jakob Krarup, Harold W. Kuhn, and Anders Lindquist.

HORS has about 90 members and each year, young people enter our society based on the recommendation of the members. The first president was Margit Ziermann (1991–1994, Budapest University

of Economy). The subsequent presidents of the society were Tamás Rapcsák (1994–1996 and 1998–2000, Computer and Automation Institute (CAI, of the HAS), Zsolt Harnos (1996–1998, University of Horticulture and Food Sciences, Budapest), Sándor Komlósi (2000–2002, University of Pécs), Tamás Szántai (2002–2004, Budapest University of Technology and Economics), László Szeidl (2004–2006, University of Pécs), and József Temesi (2006–2008, Corvinus University of Budapest). Earlier, the executive body was elected every second year. Since 2008, this period has been extended to a term of three years.

The society is also supported by institutional members. They are mostly OR-related departments of Hungarian universities and research institutes, and they represent the most important centers where OR is investigated and taught at the highest level:

CAI of the HAS;
Department of Applications of Informatics, Juhász Gyula Teacher Training Faculty, University of Szeged;
Department of Applied Mathematics, University of Miskolc;
Department of Business Methodologies, University of Pécs;
Department of Mathematics, Corvinus University of Budapest;
Department of Mathematics and Informatics, Faculty of Horticultural Science, Corvinus University of Budapest;
Department of Operations Research, Corvinus University of Budapest;
Department of Operations Research, Eötvös Loránd University, Budapest;
Faculty of Information Technology, University of Pannonia;
Institute of Informatics, University of Szeged;
Institute of Mathematics, Budapest University of Technology and Economics;

John von Neumann Faculty of Informatics, Budapest Tech Polytechnical Institution.

HORS is a member of the international OR associations of EURO and INFORMS. We have an official collaboration agreement with the German OR Society, but we also enjoy good relations with OR societies of neighboring countries even in the absence of such official relations.

The present executive board of HORS is strengthened by the following people:

István Deák (vice-president, Corvinus University of Budapest),
Csanád Imreh (University of Szeged),
Tamás Kis (treasurer, CAI, HAS),
Tamás Szántai (Budapest University of Technology and Economics).

The web page of the HORS is http://www.opkut.hu/index_en.html, where further information is available on the members and on their publications.

ACTIVITIES AND ACHIEVEMENTS OF THE SOCIETY

Research

OR activities have a rich, over 50-year-old history in Hungary. Applied mathematics research, which provides to a certain extent the theoretical base for OR theory, dates back to the turn of the last century (Farkas theorem, 1901) and is connected later to the works of König, Egerváry, Wald, and von Neumann. Applications acquired more significance in the 1970s due to the wide introduction of computers.

In the year 2008, we had a workshop dedicated to the memory of Jenő Egerváry on the occasion of the fiftieth anniversary of his death. The nine talks highlighted his contribution to the present OR methodologies, especially to the Hungarian method for the solution of the assignment problem and its relatives. Among the presentations, one provided interesting details on how Harold W. Kuhn succeeded in translating the paper of

Egerváry (originally written in Hungarian). The translation was also discussed. Based on the outcomes of the scientific meeting, a special issue of the Central European Journal on Operations Research (CEJOR) is being edited, and will appear soon.

Education

At Eötvös Loránd University of Budapest (ELUB) students of mathematics have the opportunity to specialize in OR since 1968. This specialization was introduced and organized for many years by András Prékopa and his research group at CAI of HAS. The OR Department of ELUB was established in 1983. OR specialization is available for mathematics students at the Budapest University of Technology and Economy (BUTE), and also for computer science students at the University of Szeged. Since last year, they also have a Department of Computational Optimization.

OR and/or management science, decision theory, operational management, and industrial engineering are taught at the Faculties of Business and Economics of the Corvinus University of Budapest and the University of Pécs for students of economics and business. At the agricultural schools, OR is an integral part of the management courses, agricultural informatics, and agroeconomics. In education, the emphasis is on decision models and not on the theory of OR.

After changing the scientific qualification system in Hungary, the ELUB was the first to organize PhD courses in OR. These courses belong to a more general PhD program with the title of Applied Mathematics. The first two semesters of the program have half a dozen of students. This education form started in 1993. At the Corvinus University of Budapest, and the University of Pécs OR, management science and operational management are present in the PhD program. The University of Szeged had also an OR and combinatorial optimization doctoral subprogram. A member of HORS, Boglárka Gazdag-Tóth has won the UPS-SOLA Dissertation Award of INFORMS in 2007.

The Operations Research and the Informatics Committees of the HAS composed

recently a review on the OR doctoral education in Hungary. According to this study, several degrees are acquired in this field of science every year. Doctoral education is offered now in eight Hungarian universities. The HORS has an indirect role in reviewing, evaluating, and helping OR education on various levels.

PUBLICATIONS

The HORS is one of the professional associations responsible for the editorial tasks of the CEJOR. This scientific periodical became the main English language publication forum for our researchers. Several members of our society contribute to the success of this journal as editors, authors, or reviewers. HORS also contributes financially to the publishing of CEJOR, and as compensation, some of the major OR centers in Hungary obtain a copy of the journal regularly. Hungarian OR results related to the biannual Hungarian Operations Research Conferences are published in special issues of the CEJOR.

There are two other scientific journals, the *Alkalmazott Matematikai Lapok* and *Sigma*, that publish OR-oriented papers in Hungarian. These journals have some editorial board members from HORS. Still, they play an important role in the development of Hungarian language optimization terminology and in bringing the newest OR results to the wide Hungarian OR community.

SCIENTIFIC MEETINGS

Traditionally, we used to have two scientific meeting series in Hungary, one of which, the biannual Hungarian Operations Research Conference, still exists. We just had the

twenty-eighth conference this summer. It is organized by the János Bolyai Mathematical Society, the Society of Economic Modeling, and HORS in rotation. The official language of the meeting is Hungarian, with the exception of the talks held by foreign guests. For the past decade, the best papers emerging from the talks of these meeting have been published in special issues of the CEJOR.

The other traditional series of conferences were the international conferences on mathematical programming, held regularly in Mátrafüred. These were high-level biannual English language meetings with several respected invited speakers from all over the world. The last one, the fourteenth in a row was organized in 1999. The role of these meetings are taken over by the VOCAL conference series organized in Veszprém by the University of Pannonia with the collaboration of the HORS. The best papers related to the talks are published in special issues of the journals *Optimization and Engineering* and *Optimization Methods and Software*.

HORS is proud of the success of the EURO meeting in Budapest, 2000 chaired by András Prékopa.

HORS has a prize, the Egerváry Memorial Plaque, that is awarded for exceptional Hungarian contributions to OR. The first recipient was András Prékopa, followed by Emil Klafszky in 2004, Béla Martos and Pál Rózsa in 2005, György Mészéna in 2006, József Kolumbán in 2007, and Tamás Rapcsák (posthumous) in 2008.

The Hungarian researchers are strong in inventory control and production, linear, nonlinear, and stochastic programming, combinatorial optimization, LP software. They had successful applications in inventory control, power systems, water resources, micro and macro economics.

THE KNOWLEDGE GRADIENT FOR OPTIMAL LEARNING

WARREN B. POWELL

Department of Operations Research
and Financial Engineering,
Princeton University, Princeton,
New Jersey

INTRODUCTION

There is a wide range of problems in which we need to make a decision under some sort of uncertainty, and where we have the ability to collect information in some way to reduce this uncertainty. The problem is that collecting information can be time consuming and/or expensive, so we have to do this in an intelligent way. Some examples include the following:

- We wish to find a supplier for a component who provides the lowest cost and best level of service. We know the cost, but the only way to evaluate the level of service is to try the supplier and observe actual delivery times.
- We need to find the best path through New York City to respond to certain emergencies (e.g., getting a fire truck to city hall). To evaluate the time required to traverse each path, we can try each path, or we could collect information about specific links in the network. Which paths (or links) should we measure?
- We are trying to find the best molecular compound to produce a particular result (curing cancer, storing energy, conducting electricity, etc.). There are thousands of combinations that we can try, but each test takes a day. Which compounds should we test?
- We would like to find the best price to sell a product on the internet. We

can experiment with different prices and measure sales. How do we go about testing different prices?

- We have a simulation model of an operational problem (e.g., managing takeoffs and landings at Heathrow Airport). We have a number of control parameters that we can adjust to improve performance, but running a simulation takes half a day. How do we go about trying out different parameters?
- We are running a stochastic search algorithm to solve a specific optimization problem. Each iteration takes several minutes to perform a noisy function evaluation (this might be a simulation of the climate). How do we optimize this function as quickly as possible?

These are just a small number of examples of problems where we face the challenge of collecting information to make better decisions. Applications range from business decisions, science and engineering, and simulation and stochastic optimization.

The learning problems that we wish to address all have three fundamental components: a measurement decision, which determines what information we are going to collect; the information that we obtain; and an implementation decision which uses the information. We are primarily interested in sequential problems, where we can make multiple measurements and where each measurement may depend on the outcomes of previous measurements. Our goal, then, is to design a *measurement policy* which determines how these measurements are made.

Measurement problems come in two fundamental flavors. Off-line problems use a sequence of measurements before making a final implementation decision. These arise when we have a period of time to do research before choosing a final design. The second flavor is online problems, where we collect information each time we make an implementation decision. For example, we may

want to find the best path from our new apartment in New York City to our new job. The only way to evaluate a path is to try it. The implementation decision is the choice of path to use tomorrow, but we collect information as we try the path. Off-line problems are often grouped under labels such as ranking and selection (which generally refers to choosing among a finite set of alternatives), stochastic search, and simulation optimization. Online problems are usually referred to as *bandit problems*. Our presentation of the knowledge gradient (KG) treats both off-line and online problems in an integrated way.

Information collection problems can be approached from two perspectives: frequentist and Bayesian. In the frequentist approach, we form estimates about a truth based on information drawn from a sample (see [1–4] for excellent surveys of learning from a frequentist perspective). In this article, we focus on the Bayesian perspective, where we assume that we have a prior belief about problem parameters, along with estimates of the level of uncertainty. The Bayesian perspective assumes that there is a prior distribution of possible truths, and our goal is to design a policy that discovers this truth as quickly as possible. The frequentist perspective uses noisy observations from an unknown truth to make statistical statements about this truth; the Bayesian perspective uses a prior belief and noisy measurements to create a probability distribution to describe the truth.

In this short article, we adopt a Bayesian perspective, focusing on a concept we call the knowledge gradient, which belongs to a family of methods that guides the learning process based on the marginal value of information. The roots of this idea in the field of decision theory belong to the seminal paper by Howard [5] on the value of information. We first became aware of this idea applied as a policy for off-line ranking and selection problems from Gupta and Miescke [6]. A separate line of research that uses arose in the context of optimizing unknown functions under the general name “global optimization,” with roots in the seminal paper by Kushner [7]. When these functions

can only be measured with uncertainty, this field has been referred to as *Bayesian global optimization*, with many contributions (see Jones *et al.* [8] for a good review). Our work in this area is based on Frazier and Powell [9], which analyzes the properties of sequential measurement policies based on the marginal value of a single measurement using a Bayesian framework with variance known; Frazier and Powell [10] provide an important generalization to problems with correlated beliefs (reviewed below). In parallel research, Chick and Branke [11] derive the marginal value of information for the important case where the variance is unknown using the name $LL(1)$ (linear loss, with measurement batches of one observation).

We provide a brief summary of different policies for collecting information. Although measurement policies may have a Bayesian or frequentist foundation, it is possible (and, we would argue, most natural) to evaluate any policy by sampling a truth from a prior distribution, and then determine how well a policy learns this assumed truth. This exercise then has to be repeated over many possible truths drawn from the prior.

The essential feature that separates learning problems from traditional stochastic optimization is that we are unsure about our uncertainty. If we make an observation, we are willing to update the probability distributions we use to describe uncertain parameters. Inserting this step of updating our beliefs after a measurement is made is typically referred to as *statistical learning*. When we actively make choices of what to measure, taking into account our willingness to update our beliefs, then this is optimal learning.

This article is intended to serve as a brief introduction to some of the important problem classes in optimal learning. We provide a mathematical framework for formulating and evaluating measurement policies. We review a number of heuristic policies, along with optimal policies for special problem classes. The remainder of the article focuses on the concept of the KG algorithm, which is a measurement policy that applies to a wide range of applications.

ELEMENTARY PROBLEMS

There are two elementary learning problems that provide the foundation for our discussion. Both have a discrete set of measurements $\mathcal{X} = (1, 2, \dots, M)$, where M is an integer that is “not too large,” which means that we do not have any difficulty in enumerating the choices. The first problem is known in the literature as the *multiarmed-bandit problem*, which is an online learning problem where we learn from the rewards that we receive. The second is known as the *ranking and selection problem*, where we have a budget of N measurements to evaluate each choice, after which we have to decide which alternative appears to be best.

Multiarmed Bandit Problems

The multiarmed bandit problem is based on the story of trying to choose the best of a set of M slot machines (often known as *one-armed bandits*). We do not know how much we will win each time we play a particular slot machine, but we have a distribution of belief, which we acknowledge may be wrong. We may think one machine has the highest expected reward, but we are willing to acknowledge that we may be wrong and another machine may also be the best. The only way we will learn is to try machines that do not appear to be the best. But while trying these machines, we may be earning lower rewards than we would earn by playing the machines that we think are better. The goal is to maximize the expected discounted sum of rewards that balance what we earn against what we learn (to improve future decisions).

Let μ_x be the true mean reward if we choose x . We do not know μ_x , but assume that we believe that it is normally distributed with prior mean μ_x^0 and variance $(\sigma_x^0)^2$. For convenience, we define the precision $\beta_x^0 = 1/(\sigma_x^0)^2$. Let W^n be the reward (“winnings”) we receive in the n th iteration, and let (μ^n, β^n) be our vector of beliefs about the means and precisions for all the choices after n measurements. We can write $\mu_x^n = \mathbb{E}^n \mu_x$, where $\mathbb{E}^n$ is the expectation given the first n measurements. Let $S^n = (\mu^n, \beta^n)$ be our “state of knowledge” (often referred to as the *belief state*).

We let x^n be the choice we make after n measurements, meaning that our first choice is x^0 , which is based purely on the prior. We make these measurements using a policy π , which is allowed to depend on the history of observations $W^1, W^2, \dots, W^n$. Let $X^{\pi, n}(S^n)$ be the random variable representing the decision we make, given our state S^n , and given measurement policy π . This notation allows our policy to depend on n ; if we wish to follow a stationary policy, we would write it as $X^{\pi, n}(S^n)$ (in a finite-horizon problem, the policy can depend on the number of measurements n , as well as on the belief state S^n). Our goal is to find a measurement policy π that solves

$$\sup_{\pi} F^{\pi} = \mathbb{E}^{\pi} \sum_{n=0}^N \gamma^n \mu_{X^{\pi, n}(S^n)}, \quad (1)$$

where γ is a discount factor. We write the expectation $\mathbb{E}^{\pi}$ as dependent on the policy π , which reflects assumptions on how we construct the underlying probability space. We assume that an elementary outcome is a sequence of decisions of what to measure (which depend on the policy) and the results of a particular measurement. This is not the only way to construct the probability space, but it is the one that is most often used in the research community.

In the classical multiarmed bandit problem, $N = \infty$ and $\gamma < 1$, but the finite horizon problem (possibly with $\gamma = 1$) is also of interest.

Ranking and Selection Problems

Now imagine that we have a budget of N measurements (or B dollars to spend on measurements) after which we have to choose the best of a set of M alternatives. In the bandit problem, we learn as we go, incurring rewards (or costs) as we proceed. In the ranking and selection problem, we are not concerned with how well our choices perform during the process of collecting information. Instead, we are only concerned with how well our final choice performs.

Let μ_x^N be the posterior mean of the value of alternative x after N measurements, which we chose using measurement policy π . μ_x^N is a

random variable whose distribution depends on our measurement policy. The value of using π can be written

$$F^\pi = \mathbb{E} \max_x [\mu_x^N] = \mathbb{E}^\pi \mu_{x^\pi}^N,$$

where $x^\pi = \arg \max_x \mu_x^N$ is the optimal solution when we follow measurement policy π . The problem of finding the best policy is then given by

$$\sup_{\pi \in \Pi} F^\pi.$$

We note that it is possible to write the objective as

$$\sup_{\pi} \mathbb{E} F^\pi,$$

in which case we assume that the measurement policy is built into the objective function. When we write the objective this way, it means that the probability space consists of all potential measurements W_x^n for all alternatives x and all measurements n . Alternatively, we can write the objective as

$$\sup_{\pi} \mathbb{E}^\pi F.$$

Written this way, it means that we have imbedded the policy into the probability space (a sample outcome consists of measurement alternatives and realizations), which means that F does not explicitly depend on the policy.

Notes on Objective Functions

The formulations we have given in this section assume that we are maximizing a reward. Equivalently, we could minimize the expected opportunity cost (EOC). For the ranking and selection problem, this would be written as

$$EOC = \mathbb{E} \max_x \mu_x - \mathbb{E} \mu_{x^\pi},$$

where we are measuring the value that we could achieve if we could find the best alternative using the true means, versus the value of the alternative we did choose (but again using the true means). Keep in

mind that the expectations here are over both the distribution of truths as well as the distribution over measurements. Minimizing the EOC is the same as solving

$$\sup_{\pi} \mathbb{E} \mu_{x^\pi}.$$

It is also possible to show that

$$\sup_{\pi} \sup_{\chi} \mathbb{E}^\pi \mu_{\chi(x)} = \sup_{\pi} \mathbb{E}^\pi \max_x \mu_x^N, \quad (2)$$

where χ is the policy for choosing the best alternative x given what we measure, which for our problem is defined by

$$\chi = \arg \max_x \mu_x^N.$$

Equation (2) states that if we use a measurement policy to find the best alternative x^π and we evaluate this choice using the true values μ_x , we get the same answer if we evaluate our choice using the estimates μ_x^N .

LEARNING

At the heart of any learning problem is not only uncertainty about the value of the choices we are making but also uncertainty about our uncertainty. Learning problems are easily posed in a Bayesian framework, where we are able to capture the uncertainty in our belief about a system. In our bandit or ranking and selection problems, μ_x is the true value of x , but we do not know this value. Instead, we assign a probability distribution that describes what we think μ_x is for each x . Before we start collecting any information, we might assume that our *prior* distribution of belief about μ_x is normally distributed with mean μ_x^0 and variance $(\sigma_x^0)^2$. We adopt a common convention in Bayesian analysis and define the *precision* of our belief as $\beta_x^0 = 1/(\sigma_x^0)^2$. Now assume that when we make an observation W_x^n of choice x , the precision of this measurement is known and given by β_ϵ . To reduce notational clutter, we assume that this is constant across x , but this is easily relaxed.

Assume that our current (prior) belief about choice x is given by μ_x^n and β_x^n , and

that we choose to measure alternative $x^n = x$. We would then observe W_x^{n+1} , which is unknown when we picked x^n . Further assume that our prior is normally distributed (i.e., $\mu_x \sim N(\mu_x^0, 1/\beta_x^0)$), and that $W_x^{n+1} = \mu_x + \varepsilon_x^{n+1}$, where ε_x^{n+1} is also normally distributed with precision β_ϵ . Bayes theorem can be used to show that our updated mean and precision of the posterior belief can be computed using

$$\mu_x^{n+1} = \frac{\beta_x^n \mu_x^n + \beta_\epsilon W_x^{n+1}}{\beta_x^n + \beta_\epsilon}, \quad (3)$$

$$\beta_x^{n+1} = \beta_x^n + \beta_\epsilon. \quad (4)$$

We also have the property that, if our prior belief about μ is normally distributed, then the posterior belief is normally distributed.

MEASUREMENT POLICIES

Our central challenge is designing a policy for collecting information. For off-line problems, these policies guide information collection that determines the final decision. For on-line problems, our policy has to strike a balance between receiving rewards (or incurring costs) and collecting information that will help future decisions.

Measurement policies can be deterministic or sequential. If we are using a deterministic policy, decisions about what to measure are made before any measurements are learned. Deterministic policies can be optimal for certain types of statistical learning problems. Our interest is in sequential problems, where the next measurement decision is made only after learning the value of the previous measurement.

We begin by showing that optimal measurement policies can be characterized using a simple dynamic programming formulation. The problem is that the dynamic program cannot be solved exactly. We then describe a series of simple heuristic policies that are often used in the research community.

Optimal Sequential Policies

Dynamic programming is widely used for sequential decision problems. For our problem, we start in a (knowledge) state S^n ,

then we take an action (measurement) x^n , and observe a random outcome W_x^{n+1} , which takes us to a new state according to the transition function $S^{n+1} = S^M(S^n, x^n, W_x^{n+1})$ defined by Equations (3) and (4). Our optimal measurement x^n can, in theory, be characterized using Bellman's equation

$$V(S^n) = \max_x (C(S^n, x) + \gamma \mathbb{E} \{ V(S^{n+1}) | S^n \}). \quad (5)$$

Here, $V(S^n)$ captures the value of being in a particular knowledge state S^n . Using the principle of dynamic programming, this is given by choosing the measurement action x that maximizes the contribution earned (this might be a negative cost) from taking action x , plus the value of being in the knowledge state S^{n+1} that results from this action, given by $V(S^{n+1})$. Of course, S^{n+1} is random given S^n and x , so we have to take its expectation over the measurement W_x^{n+1} for each alternative x . For off-line problems, $C(S^n, x)$ may be zero, since we do not receive any value until we pick the final design. For online problems, $C(S^n, x)$ would be the expected reward μ_x^n .

So, if Equation (5) gives us the optimal measurement policy, why do we not just use this solution? The reason is that we just do not have algorithms to solve dynamic programs when the state variable is a vector of continuous parameters. There is, however, a special case that can be solved optimally without directly solving the dynamic program, which uses the concept of Gittins indices for multiarmed bandit problems. After presenting this idea, we review the most popular heuristic policies. Our presentation focuses purely on sequential policies where the choice of the n th measurement depends on the prior and the outcomes of $W^1, \dots, W^n$. We then close by introducing the KG policy and illustrate the wide range of information collection problems that can be addressed using this strategy.

Gittins Indices for Multiarmed Bandit Problems

In 1974, Gittins and Jones [12] found that the multiarmed bandit problem (specifically, the infinite horizon version of the multiarmed

bandit problem) could be solved optimally using an index policy computed using

$$\Gamma(\mu_x^n, \sigma_x^n, \sigma_\epsilon, \gamma) = \mu_x^n + \Gamma\left(0, \frac{\sigma_x^n}{\sigma_\epsilon}, 1, \gamma\right) \sigma_\epsilon. \quad (6)$$

In this expression, $\Gamma(\mu_x^n, \sigma_x^n, \sigma_\epsilon, \gamma)$ is the Gittins index for measurement x for which the belief is μ_x^n and the standard deviation is σ_x^n . $\sigma_\epsilon = \sqrt{1/\beta_\epsilon}$ is the standard deviation of the measurement and γ is the discount factor. The Gittins index policy, as it became known in the literature, specifies that you measure the choice x with the highest value of $\Gamma(\mu_x^n, \sigma_x^n, \sigma_\epsilon, \gamma)$. The power of this policy is that there is one index per choice, and at no time are we dealing with multidimensional state vectors.

This leaves us with the challenge of computing $\Gamma(\mu_x^n, \sigma_x^n, \sigma_\epsilon, \gamma)$. Equation (6) shows us that we can compute the index as a function of a simpler index $\Gamma\left(0, \frac{\sigma_x^n}{\sigma_\epsilon}, 1, \gamma\right)$. This has a close parallel with the standard normal distribution (indeed, this relationship depends on normally distributed beliefs). While this relationship simplifies the problem, we still have to find $\Gamma\left(0, \frac{\sigma_x^n}{\sigma_\epsilon}, 1, \gamma\right)$, which requires the fairly difficult numerical solution of an integral equation.

Fortunately, there have been recent efforts to develop numerical approximations. Brezzi and Lai [13] found that

$$\Gamma(0, s, 1, \gamma) = \sqrt{-\log \gamma} \, b\left(-\frac{s^2}{\log \gamma}\right), \quad (7)$$

where the function $b(\cdot)$ has to be approximated. Chick and Gans [14] improved on the initial approximation of this function by Brezzi and Lai [13], proposing

$$b(\zeta) \approx \begin{cases} \frac{\zeta}{\sqrt{2}} & \zeta \leq \frac{1}{7} \\ \exp\left(\frac{-0.02645(\log \zeta)^2}{+0.89106 \log \zeta - 0.4873}\right) & \frac{1}{7} < \zeta \leq 100 \\ \sqrt{\zeta} \sqrt{\zeta \log \zeta - \log \log \zeta - \log 16\pi} & \zeta > 100. \end{cases} \quad (8)$$

The Gittins index policy is specifically designed for on-line problems, and in particular infinite horizon bandit problems. However, the structure of the policy offers

some insights into the information-collection process, as we see below.

Heuristic Policies

There are a number of simple policies that can be used for collecting information. The policies reviewed below are the most popular. These can generally be adapted for on-line or off-line applications.

- *Pure Exploration.* Pure exploration involves picking choices at random. If there are M choices, we might choose $x^n = x$ with probability $1/M$ or use some other exogenously driven process. A pure exploration strategy makes little sense in an on-line application, but it can be useful (if not optimal) for off-line problems, especially for high-dimensional applications where the measurement space $\mathcal{X}$ is quite large. For off-line problems, we may use pure exploration just to collect data to fit a statistical model.
- *Pure Exploitation.* We make the decision that appears to be best, given what we know. Stated mathematically, a pure exploitation policy would be written as

$$x^n = \arg \max_{x \in \mathcal{X}} \mu_x^n.$$

Pure exploitation can be effective for online learning where the prior information is quite good.

- *Mixed Exploration and Exploitation.* Here we explore with some probability ρ , and exploit with probability $1 - \rho$. A variation is epsilon-greedy exploration, where we explore with probability $\rho^n = c/n$, where c is a tunable parameter.
- *Boltzmann Exploration.* Here we explore with probability

$$\rho_x^n = \frac{\exp(\theta \mu_x^n)}{\sum_{x' \in \mathcal{X}} \exp(\theta \mu_{x'}^n)},$$

where θ is a tunable parameter. $\theta = 0$ produces pure exploration, while as θ increases, it approaches pure

exploitation. This policy explores in a more intelligent way than the more classical exploration policies.

- *Interval Estimation.* Interval estimation is the most sophisticated of this group of heuristics. Here, we compute an index using

$$v_x^n = \mu_x^n + z_\alpha \bar{\sigma}_x^n. \quad (9)$$

In this policy, z_α is a tunable parameter, and $\bar{\sigma}_x^n$ is the standard deviation of our estimate μ_x^n . This policy strikes a balance between the estimate μ_x^n (low values are less likely to be tested), and the uncertainty with which we know μ_x^n . The policy rewards higher levels of uncertainty, but only if μ_x^n is competitive.

It is useful to compare the index policy given by interval estimation in Equation (9) with the Gittins index policy, given in Equation (6). Both policies compute an index given by the current belief plus an additional “bonus” (often referred to as the *uncertainty bonus*). How this bonus is computed is where the two policies differ. The Gittins policy uses a theoretically derived factor that declines to zero as the number of observations increase. This is multiplied by the standard deviation σ_ϵ of the measurement error. For interval estimation, the bonus is a constant factor (which has to be tuned) times the standard deviation $\bar{\sigma}_x^n$ of our estimate μ_x^n , which then declines with the number of observations. As the number of times we measure an alternative increases, the factor $\Gamma\left(0, \frac{\sigma_\epsilon^n}{\sigma_\epsilon}, 1, \gamma\right)$ in Equation (6) decreases (σ_ϵ stays the same). By contrast, with interval estimation, it is $\bar{\sigma}_x^n$ that decreases, while z_α stays the same.

Policies from Simulation Optimization

An entire body of research has developed around the problem of choosing the best set of parameters to guide a simulation. If these parameters are discrete, and if we fix the length of the simulation, this problem falls under the umbrella of ranking and selection if we are considering a finite number of alternatives. Simulation optimization

introduces the additional dimension that we can choose the length of the simulation, but we may face a budget on the total computing time. This problem was first addressed under the name of “optimal computing budget allocation” (OCBA) by Chen [15]. This idea has subsequently been studied in a number of papers [16–19]. Chick and Inoue [20] introduces the *LL(B)* strategy, which maximizes the linear loss with measurement budget B . He and Chick [21] introduce an OCBA procedure for optimizing the expected value of a chosen design, using the Bonferroni inequality to approximate the objective function for a single stage. A common strategy in simulation is to test different parameters using the same set of random numbers to reduce the variance of the comparisons. Fu *et al.* [22] apply the OCBA concept to measurements using common random numbers.

There is also a substantial body of literature that is often grouped under the heading of stochastic search, which addresses problems where we are searching for the best of a continuous set of parameters. For a thorough review of this field, see Spall [23]. We note, however, that this field covers numerous algorithms such as stochastic approximation methods that we would not classify as falling under the heading of optimal learning.

EVALUATING POLICIES

When faced with an array of different learning policies, we have to address the problem of evaluating policies. Using the setting of online problems, we start by observing that we generally cannot compute the expectation in Equation (1) exactly, but this equation hints at how we might evaluate a policy in practice. Let ω index both a prior $\mu(\omega)$ and a sequence of observations of $W^1(\omega), W^2(\omega), \dots, W^N(\omega)$, which depend on the prior, where

$$W_x^n(\omega) = \mu_x(\omega) + \epsilon_x^n(\omega).$$

Recall that $X^{\pi,n}(S^n(\omega))$ is our decision rule (policy) for choosing an alternative to test given our state of knowledge S^n . Given a sample path ω , a sample realization of a measurement policy would be computed using

$$F^\pi(\omega) = \sum_{n=0}^N \gamma^n \mu_{X^\pi, n(S^n(\omega))}(\omega). \quad (10)$$

Finally, we can repeat this simulation K times to form a statistical estimate of the value of a policy

$$\bar{F}^\pi = \frac{1}{K} \sum_{k=1}^K \sum_{n=0}^N \gamma^n \mu_{X^\pi, n(S^n(\omega^k))}(\omega^k). \quad (11)$$

Now we use standard statistical tools to compare policies.

We view this method of evaluating policies as being fundamentally Bayesian, since we depend on a prior to determine the set of truths. However, the policy we are testing could be frequentist. A frequentist testing strategy might involve simulating a policy (Bayesian or frequentist) on a single function, where we start by assuming that we have no knowledge of the function (we can treat it initially as a constant), and where measurements of the function are noisy. While this strategy is not uncommon, it introduces dangers. For example, it may be possible to choose a policy that works well on a particular function. This problem can be mitigated by running the algorithm on a family of functions, but then this is comparable to generating a truth (the set of truths would be given by the family of functions).

THE KNOWLEDGE GRADIENT POLICY

A simple idea for guiding information collection is to choose to measure the alternative that provides the greatest value from a single measurement. This idea was first introduced for ranking and selection problems by Gupta and Miescke [6] as the $(R_1, \dots, R_1)$ procedure. It has since been studied in greater depth as the knowledge gradient by Frazier and Powell [9] for problems where the measurement noise is known, and by Chick and Branke [11] under the name of $LL(1)$ (linear loss with batch size 1) for the case where the measurement noise is unknown. The idea was recently applied to on-line problems [24] for multiarmed bandit problems with both independent and correlated beliefs.

The “breakthrough,” if it can be called this, with the idea of the knowledge gradient is the growing amount of empirical evidence that it appears to work well, even when competing against optimal policies such as Gittins indices for classical multiarmed bandit problems. This seems surprising, given that optimal learning problems can be formulated as dynamic programs. As a general statement, myopic policies often work poorly for dynamic problems, and the KG policy is effectively a myopic heuristic. The insight that our numerical work appears to be showing is that, while this expectation is certainly true in the context of dynamic problems that arise in the management of physical resources, it does not appear to hold true in the context of learning problems.

The Knowledge Gradient for Off-Line Learning

As before, we assume that all beliefs are normally distributed with parameters captured by the state $S^n = (\mu_x^n, \beta_x^n)_{x \in \mathcal{X}}$. Given S^n , which means, given our beliefs about each choice μ_x^n , the value of our current state of knowledge is given by

$$V^n(S^n) = \max_{x' \in \mathcal{X}} \mu_{x'}^n.$$

Now assume that we choose to measure $x^n = x$. This means that we get to observe W_x^{n+1} and update our belief about μ_x . We write this updating process using our transition equation $S^{n+1}(x) = S^M(S^n, x^n, W^{n+1})$. This means applying the Bayesian updating Equations (3) and (4), but only for choice x . With this new information, the value of our new state of knowledge S^{n+1} would be given by

$$V^{n+1}(S^{n+1}(x)) = \max_{x' \in \mathcal{X}} \mu_{x'}^{n+1}.$$

At iteration n , however, the observation W^{n+1} is a random variable, which means that $V^{n+1}(S^{n+1}(x))$ is a random variable. We can compute the expected value of measuring x as

$$v_x^{\text{KG}, n} = \mathbb{E} [V^{n+1}(S^{n+1}(x)) - V^n(S^n) | S^n]. \quad (12)$$

We refer to $v_x^{\text{KG}, n}$ as the KG since it is the marginal value of information from

Table 1. Calculations Illustrating the Knowledge Gradient Index

Measurement	μ	$\bar{\sigma}$	β	$\tilde{\sigma}$	ζ	$f(\zeta)$	$v_x^{\text{KG},n}$
1	20.0	18.00	0.0031	17.999	-0.444	0.215	3.878
2	22.0	12.00	0.0069	11.998	-0.500	0.198	2.373
3	24.0	25.00	0.0016	24.999	-0.160	0.324	8.101
4	26.0	12.00	0.0069	11.998	-0.167	0.321	3.853
5	28.0	16.00	0.0039	15.999	-0.125	0.340	5.432

measuring x . Note that the KG policy not only captures what we learn about the mean of a choice but also the change in the precision of our belief. We write the KG policy as choosing to measure the alternative x which has the highest marginal value of information. We write this policy simply as

$$X^{\text{KG},n} = \arg \max_{x \in \mathcal{X}} v_x^{\text{KG},n}. \quad (13)$$

We start by computing the variance of the change in our estimate of μ_x given our state of knowledge S^n , given by

$$\tilde{\sigma}_x^{2,n} = \text{Var}[\mu_x^{n+1} - \mu_x^n | S^n].$$

It is fairly straightforward to show that

$$\begin{aligned} \tilde{\sigma}_x^{2,n} &= \bar{\sigma}_x^{2,n} - \bar{\sigma}_x^{2,n+1}, \\ &= \frac{(\bar{\sigma}_x^{2,n})}{1 + \sigma_\epsilon^2 / \bar{\sigma}_x^{2,n}}. \end{aligned} \quad (14)$$

We then compute the distance between our current estimate of the value of x , and the best of the rest, normalized by the number of standard deviations in the measurement of the change, given by

$$\zeta_x^n = - \left| \frac{\mu_x^n - \max_{x' \neq x} \mu_{x'}^n}{\tilde{\sigma}_x^n} \right|.$$

Next, we use a standard formula for $\mathbb{E} \max\{0, Z + \zeta\}$, where Z is the standard normal deviate. This formula is given by

$$f(\zeta) = \zeta \Phi(\zeta) + \phi(\zeta),$$

where $\Phi(\zeta)$ and $\phi(\zeta)$ are respectively the cumulative standard normal distribution and the standard normal density. Finally, the KG is given by

$$v_x^{\text{KG},n} = \tilde{\sigma}_x^n f(\zeta_x^n).$$

For a more detailed development of these equations, see [9]. Table 1 provides an illustration of the calculations for a simple problem with five alternatives.

On-Line Learning

The ranking and selection problem has a long history that has evolved completely independently of the multiarmed bandit problem. However, we can take the basic idea of the KG policy and apply it to the multiarmed bandit problem. We have to find the expected value of a single measurement. For on-line problems, we approach this by assuming that we are going to do a single step from which we can learn and update our beliefs about the problem. After that, we continue making decisions holding our state of knowledge constant.

If we have an on-line learning problem where we have only two trials, this means we can learn from the first trial and use it in the second trial. The value of measuring x would simply be $v_x^{\text{KG},n}$, which measures the improvement in our ability to solve the problem in the second trial.

Now imagine that we have N trials, where we have already made $n - 1$ measurements and are thinking about what we should do for the n th measurement. Since this is an on-line problem, the expected reward we will receive by measuring x is μ_x^n . In addition, we get the benefit of using this information $N - n$ more times in later decisions. Using this reasoning, we can find the on-line knowledge gradient (OLKG) using

$$v_x^{\text{OLKG},n} = \mu_x^n + (N - n)v_x^{\text{KG},n}.$$

If we have an infinite horizon problem (as with the standard multiarmed bandit problem) with discount factor γ , the OLKG policy would be

$$v_x^{\text{OLKG},n} = \mu_x^n + \frac{\gamma}{1-\gamma} v_x^{\text{KG},n}.$$

Again note the comparisons against the Gittins index policy and the interval estimation policy, both of which use the expected reward from a single measurement, and a term that in some way captures the value of information on future decisions (although the OLKG policy is the only one of these policies where this is explicit). Unlike these other two policies, on-line KG is not a true index policy, since $v_x^{\text{KG},n}$ depends on a calculation that requires information from all the other choices. The Gittins and IE index policies compute an index that is based purely on parameters from a particular choice.

This idea is developed with much greater rigor in Ryzhov *et al.* [24], which also reports on comparisons between the OLKG policy and other policies. It was found that the KG policy actually outperforms Gittins indices even when applied to multiarmed bandit problems (where Gittins is known to be *optimal*) when we use the approximation in Equation (8). KG also outperforms pure exploitation (i.e., for on-line problems), but it slightly underperforms interval estimation when the parameter z_α is carefully tuned. However, it was also found that IE is sensitive to this tuning, and even slight deviations from the best value of z_α can produce results that underperform KG.

The S-Curve Problem

An issue with the KG is that the value of information can be nonconcave. It is not hard to create problems where a single measurement adds very little value, since the noise in the observation is too high to change a decision. We can easily find the value of information by computing the KG where the precision of a measurement x is given by $n_x \beta_\epsilon$ rather than just β_ϵ . Think of it as making a single measurement with precision $n_x \beta_\epsilon$ instead of β_ϵ . An example of a curve where the value of information is nonconcave is given in Fig. 1.

The issue of the nonconcavity of information is well known. Howard [5] demonstrates the nonconcavity of information in the context of an auction problem. Radner and Stiglitz [25] discusses the problem in

considerably greater depth, giving general conditions under which the value of information is not concave. This research has been extended more recently by Chade and Schlee [26] and Delara and Gilotte [27] to more general settings.

The issue is discussed in Frazier and Powell [28] in the context of sequential sampling. This paper proposes a modification of the KG policy, which is dubbed KG(*). In this policy, we find the value of n_x , which maximizes the average value of information, as depicted in Fig. 1. We note that in a budget-constrained setting, we may not have the budget to do n_x measurements, in which case we have to consider the value of a smaller number of measurements. Further, we may not wish to use our entire budget on a single alternative, which may eliminate alternatives that require a large number of measurements to evaluate.

Correlated Beliefs

The KG policy is able to handle the very important case of correlated beliefs. This arises when measuring x may tell us something about x' . For example, imagine that we are testing the set of features in a product, or we want to identify the best set of drugs to put into a drug treatment, or we want to evaluate the best set of energy saving technologies in a house. These are all instances of subset (or portfolio) selection problems, where a choice x might be given by

$$x = (0, 1, 1, 0, 1, 0, 0, 0).$$

Now consider a choice x' given by

$$x' = (0, 1, 1, 0, 0, 1, 0, 0).$$

x and x' share two common members, so it might be reasonable to expect that, if x performs better than expected, that x' will perform better than expected. Let Σ^0 be our initial estimate of the covariance in our belief between different alternatives, where Σ^0 has $|\mathcal{X}|$ rows and columns. Also, let $B^n = (\Sigma^n)^{-1}$ be the inverse of the covariance matrix (think of this as the matrix version of our precision). Assume that we measure $x^n = x$, observing W_x^{n+1} . Recalling that μ^n is our vector of

Figure 1. Illustration of the nonconcavity of information, and the maximum average value that would be used by the KG(*) algorithm.

beliefs, let $\mu^{n+1}(x)$ be the updated vector of beliefs assuming we measure $x = x^n$, and let $\Sigma^{n+1}(x)$ be the updated matrix of covariances. The Bayesian formulas for updating means and covariances, in the presence of correlated beliefs, are given by

$$\begin{aligned}\mu^{n+1}(x) &= \Sigma^{n+1}(x) \left(B^n \mu^n + \beta_\epsilon W_x^{n+1} e_x \right), \\ B^{n+1}(x) &= B^n + \beta_\epsilon e_x (e_x)^T,\end{aligned}$$

where e_x is a column vector of 0s with a 1 in the element corresponding to alternative x .

For our purposes, there is a more convenient way of expressing the updating of the vector μ^n . First, let $\tilde{\Sigma}^n(x)$ be the change in the covariance matrix for μ^n due to measuring alternative x , just as $\tilde{\sigma}_x^{2,n}$ was the change in the variance of μ_x^n due to measuring x . This is given by

$$\begin{aligned}\tilde{\Sigma}^n(x) &= \Sigma^n - \Sigma^{n+1}(x) \\ &= \frac{\Sigma^n e_x (e_x)^T}{\sqrt{\Sigma_{xx}^n + \lambda W}}.\end{aligned}$$

Next let $\tilde{\sigma}^n(x)$ be the column vector of $\tilde{\Sigma}^n(x)$ corresponding to alternative x , given by

$$\tilde{\sigma}^n(x) := \tilde{\Sigma}^n(x) e_x. \quad (15)$$

Also, let $\tilde{\sigma}_i^n(x) = (e_i)^T \tilde{\sigma}^n(x)$ be the i th component of the vector $\tilde{\sigma}^n(x)$.

Let $\text{Var}^n[\cdot] = \text{Var}[\cdot | S^n]$ be the variance given all the measurements up through iteration n . We observe that we can write

$$\begin{aligned}\text{Var}^n [W_x^{n+1} - \mu_x^n] &= \text{Var}^n [W_x^{n+1}] \\ &= \text{Var}^n [\mu_x + \varepsilon_x^{n+1}] \\ &= \Sigma_{xx}^n + \sigma_\epsilon^2,\end{aligned}$$

where the last step follows from the independence between the belief about the variance of μ_x conditioned on S^n , and the noise in the $n + 1$ st measurement ε_x^{n+1} . Now let

$$Z^{n+1} := (W^{n+1} - \mu^n) / \sqrt{\text{Var}^n [W^{n+1} - \mu^n]},$$

where $\text{Var}^n [W^{n+1} - \mu^n] = \Sigma_{xx}^n + \sigma_\epsilon^2$. It is straightforward to show that Z^{n+1} is normally distributed with mean 0 and variance 1. We can now write the updating equation using

$$\mu^{n+1} = \mu^n + \tilde{\sigma}^n(x^n) Z^{n+1}. \quad (16)$$

Also, it is easy to see that $\text{Var} Z^{n+1} = 1$ (since we constructed it that way).

The KG policy for correlated measurements is computed using

Figure 2. Regions of z over which different choices dominate. Choice 2 is always dominated.

$$\begin{aligned} \nu_x^{\text{KG}} &= \mathbb{E} \left[\max_i \mu_i^{n+1} \mid S^n = s, x^n = x \right] \\ &= \mathbb{E} \left[\max_i \mu_i^n + \tilde{\sigma}_i^n(x^n) Z^{n+1} \mid S^n, x^n = x \right], \end{aligned} \quad (17)$$

where Z is a scalar random normal variate.

Our challenge now is computing this expectation, which is much harder for correlated beliefs, but the computation is very manageable. We start by defining

$$\begin{aligned} h(\mu^n, \tilde{\sigma}^n(x)) &= \mathbb{E} \left[\max_i \mu_i^n + \tilde{\sigma}_i^n(x^n) Z^{n+1} \mid S^n, x^n = x \right]. \end{aligned} \quad (18)$$

Substituting Equation (18) into Equation (17) gives us

$$X^{\text{KG}}(s) = \arg \max_x h(\mu^n, \tilde{\sigma}^n(x)). \quad (19)$$

Let $h(a, b) = \mathbb{E}(\max_i a_i + b_i Z)$, where $a_i = \mu_i^n$, $b_i = \tilde{\sigma}_i^n(x^n)$ and Z is our standard normal variate. a and b are M (or $|\mathcal{X}|$)-dimensional vectors of means and $\tilde{\sigma}$'s. Now sort the elements of the vector b so that $b_1 \leq b_2 \leq \dots$, giving us a sequence of lines with increasing slopes. Looking at the lines $a_i + b_i z$ and $a_{i+1} + b_{i+1} z$, we find they intersect at

$$z = c_i = \frac{a_i - a_{i+1}}{b_{i+1} - b_i}.$$

Assume that $b_{i+1} > b_i$. If $c_{i-1} < c_i < c_{i+1}$, then there should be a range for z over which a

particular choice dominates, as depicted in Fig. 2. It is possible that a choice is always dominated, which will happen if $c_{i+1} < c_i$ (see choice 2 in the Fig. 2). If this happens, we simply drop the choice from the set, producing a new set of choices with coefficients $\tilde{a}_i, \tilde{b}_i$ and intersections $\tilde{c}_i$, which satisfy $c_{i-1} < c_i < c_{i+1}$.

Once we have sorted the slopes and dropped dominated alternatives, we can compute Equation (17) using

$$h(a, b) = \sum_{i=1}^M (b_{i+1} - b_i) f(-|c_i|),$$

where, as before, $f(z) = z\Phi(z) + \phi(z)$. Note that the summation over alternatives has to be adjusted to skip any choices i that were found to be dominated. For a more detailed presentation, see Frazier *et al.* [10].

The ability to handle correlated beliefs is a major generalization, and one which is not possible with the other heuristic search rules or Gittins indices. There are numerous practical problems where these correlations might be expected to arise. For example, if we are measuring a continuous function, we would expect our beliefs about x and x' to be correlated in proportion to the distance between x and x' . Correlated beliefs make it possible to tackle problems where the measurement budget is potentially much smaller than the number of potential measurements.

There is a limited but growing literature on bandit problems (online learning problems) where there is structure among the alternatives. Berry and Fristedt [29], Chapter 2 consider the case of correlated

beliefs, but do not provide a method to solve it. Pandey *et al.* [30] introduces the notion of dependent arms where alternatives can be grouped into clusters of arms with similar behavior. The choice is then reduced to one of choosing among clusters. Presman and Sonin [31] introduces the idea of bandit problems with hidden state variables, which creates dependencies among different alternatives. There is a small but growing literature on problems where correlations are introduced by assuming an underlying functional form for the belief [32].

Finally, there are a number of papers that deal with the important special case of continuous functions. Ginebra and Clayton [33] studies “response surface bandits” where the measurements are continuous; they introduce a simple heuristic (basically an uncertainty bonus similar to Gittins indices) for learning a surface. Agrawal [34] considers learning a multidimensional surface, but this is accomplished by sampling the function at equally spaced points, and then combining the results to produce an estimate of the function using kernel regression [35]. Kleinberg [35] improves on this by sampling over evenly spaced intervals, but then applying a standard bandit algorithm to the resulting finite set of points (there is no evidence that correlations are being used in the choice of what to measure).

Other Applications of the Knowledge Gradient

Now that we have shown that we can use the KG concept for on-line and off-line problems, as well as the important class of correlated beliefs, it is natural to ask the following question: what is the scope of applications of the KG for guiding information collection? We have only begun to explore the potential range of applications, but some examples include the following:

- *Learning on Graphs.* Consider the problem of making measurements so that we can better learn the costs on an uncertain graph. For example, we need to find the best path for an emergency response vehicle, and we have to send people to measure the costs on specific links of the network to produce the best

solution to our shortest path problem. Ryzhov and Powell [36] shows that we can identify the best link to evaluate using a method that is very similar to the KG for independent beliefs.

- *Drug Discovery.* Negoescu *et al.* [37] consider the problem of finding the best molecular compound, through intelligent sequencing of laboratory experiments. The research used a linear regression model to capture beliefs, reducing a problem with 87,000 possible compounds to one involving only 200 regression parameters. The KG policy was able to identify a compound very close to the best in under 100 experiments.
- *Subset Selection.* Ryzhov and Powell [38] shows how the KG can be used to guide the selection of the best set of energy-saving technologies to implement in a building, recognizing that different technologies interact in different ways for a particular building.
- *Optimizing General Surfaces.* The KG for correlated beliefs presented in this article requires that the covariance matrix Σ^0 be known. In Mes *et al.* [39], the KG concept is adapted to a problem for optimizing general functions, which may be nonconcave and which can be a function of discrete or categorical variables. The method uses statistical representation where the function is approximated using a weighted sum of estimates at different levels of aggregation. The KG is proven to find the optimum of the function in the limit, and appears to show good empirical convergence.

The KG has other useful theoretical properties. Frazier and Powell [9] shows that the KG policy is optimal (for any measurement budget) if there are only two choices, and that, for off-line problems, the policy is asymptotically optimal, which means that in the limit it will find the best alternative. Of course, many heuristic policies are asymptotically optimal (again, this applies only to off-line problems), but the KG algorithm is the only stationary policy that is both myopically optimal

(which KG is by construction) and asymptotically optimal. This may be a reason why it appears to offer good empirical performance for intermediate measurement budgets.

The KG does not always work. It might consistently work well if the value of information is concave in the measurement budget, but this is not always the case. The marginal value of information may initially be quite small, when a single measurement is not enough to change a decision. But it may happen that, after some number of measurements, the marginal value starts to grow. This might arise, for example, if we are trying to find the best hitter for a baseball team. Watching a hitter for a few at bats teaches us almost nothing. It can take several hundred at bats before we can confidently say that one hitter is better than another. The value of information can then follow an S-curve, which means that it can be highly nonconvex for some applications.

The KG offers the type of general strategy for collecting information that steepest ascent has offered for a wide range of nonlinear maximization problems. It may not work best for all applications, but it may provide a valuable starting point for a wide range of problems.

THE LAW AND ECONOMICS OF RISK REGULATION

CARY COGLIANESE
University of Pennsylvania Law
School, Philadelphia,
Pennsylvania

From the origins of the common law era to the present day regulatory state, governments have always used law as a means of risk management. Today law plays a central role in managing a variety of risks associated with the modern economy. The many laws governing financial institutions and investment practices seek to protect society from undesirable economic risks such as fraud or insolvency. Other laws regulate manufacturing operations in an attempt to protect workers from occupational risks and neighbors from environmental risks. Laws seek to protect consumers from injuries arising from unsafe products, travelers from transportation accidents, and all citizens from risks of criminal or terrorist violence.

Given law's important role in addressing risk in society, scholars have devoted considerable attention to risk regulation, with both normative and positive research. An initial normative question has centered on the justifications for governmental regulation of the marketplace [1]. Accepting the need for risk regulation, researchers have studied, as a positive matter, the process by which regulatory standards are established and implemented, as well as have evaluated whether alternative decision-making procedures achieve their intended objectives. A central substantive issue in risk regulation focuses on the proper level of risk protection that regulatory standards should strive to achieve. Whatever the level of appropriate risk protection, a final issue considers the form or design of risk regulatory instruments. Much research in recent decades on the regulation of health, safety, and environmental risks has focused on each of these issues in

an effort to contribute policy-relevant knowledge for those officials who seek to use law as means of risk management.

THE BASIS FOR RISK REGULATION

In theory, the common law of contracts, which allows the participants in market transactions to allocate economic risks between themselves, might initially be thought to be the only law needed for purposes of risk management. If individuals faced no transaction costs and possessed perfect information about the risks of different activities, they could presumably bargain with each other so that society's most valued economic activities would continue while taking optimal measures to protect those who would be harmed from such activities [2]. Those consumers who want to pay more for risk reduction can do so, and the market in principle should adjust to meet individuals' varied demands for safety. But "the difficulty here, of course, is that markets are far from perfect" (3, p. 82). Given the existence of transaction and information costs, contracting over risk does not occur in an optimal manner. As a result, even under the common law, judges recognized that other legal principles, namely, tort principles of nuisance and, more recently, of products liability were needed both to provide compensation to injured individuals and also to serve as a disincentive for socially suboptimal risky activity [4,5].

The threat of tort liability serves to deter risky behavior, especially given the size of some jury awards [6,7], and in this way tort law can be said to fulfill a "regulatory" function by inducing more optimal levels of care. Tort law in principle holds certain advantages as a regulatory mechanism [8]. Unlike the often tightly defined prescription of contemporary regulation, the open-ended standards of the common law (such as "unreasonable" harm) makes liability more readily adaptable to changing circumstances.

Rather than prospectively addressing sometimes speculative risks, common law liability applies only to harms that actually occur, and it also places the principal decision-making authority in the hands of judges who may be far less subject to interest group pressures than legislators or regulatory officials. Finally, when liability rules place no-fault responsibility on the least-cost avoider of the risk, this can induce firms to produce safer products and processes [9]. Insurance coverage can provide further incentives for risk reduction, because insurance companies can set premiums based on risk levels and condition coverage on compliance with basic safety principles [1].

On the other hand, some of these same purported advantages of tort law can be disadvantages [8]. For example, judges may well be more independent, but they are also much less knowledgeable about science and risk analysis than are experts within centralized regulatory agencies. More significantly, tort liability may provide less-than-optimal levels of deterrence for society. Despite their theoretical advantages for pricing risk, liability insurance markets may, like any market, operate imperfectly or may not cover all types of harms. The availability of bankruptcy may also blunt some of the deterrent effects of tort liability. Business decision makers may underestimate the probability that their activities will cause harm to others, thereby underestimating their liability for such harm [10,11]. The litigation process itself can be slow and costly, both for society as well as for plaintiffs seeking recovery, which may keep some number of meritorious cases from being pursued. The injured party bears the burden of proof, and especially when injured parties are poor, they may not pursue litigation at a level needed to create a socially optimal level of deterrence. In addition, when there are many injured parties (such as in cases of pollution or major industrial accidents), these individuals will face collective action problems in organizing to seek recovery [12]. If many individuals are harmed only slightly, the overall level of harm to society may still vastly exceed the overall benefits from the underlying economic activity, but each individual will have little reason to

pursue costly litigation. As a result of these limitations, the level of deterrence provided by tort liability will often prove to be much lower than is socially desirable [7].

For these kinds of reasons, regulation has been recognized as necessary to supplement, or even replace, common law liability [13]. Regulation—that is, imposing more specific, prospective risk reduction requirements—is preventive rather than reactive. Regulatory intervention in the marketplace has been generally viewed as justified in instances of market failure such as information asymmetries (consumer product risks or workplace health and safety risks) and negative externalities (environmental risks or major industrial or nuclear power accidents) [14,15]. As a result, although common law liability remains in place, the rate of regulation has grown dramatically over the last century and regulatory agencies, rather than courts, have today become the primary source of law affecting risk management.

THE PROCESS OF RISK REGULATION

Given the critical role of regulation, scholars have focused on how regulatory agencies make law. Although the normative case for regulation to address market failures has been generally accepted, this does not mean that all regulation is motivated by such public interested reasons nor that adequate levels of regulation will always be put in place. On the contrary, positive research on the process of regulation has suggested that risk regulation can depart from normative ideals and instead fall prey to the dictates of interest group and electoral politics [16]. Businesses that would incur costs under regulation can be expected to oppose the establishment of stringent regulation, and they are better organized in the policy process than are the beneficiaries of regulation, who may be numerous but who have only diffuse interests at stake [17]. As a result, government may undersupply public regulatory protection just as with common law protection. The same collective action problems that serve as a barrier to tort litigation in cases of diffuse and unorganized victims of pollution or other harms

may also dampen the pressure for regulatory responses to such harms.

The close, interactive relationships that arise between government and industry can potentially lead to regulatory capture, a situation where government protects an industry's interests at the expense of the broader public's interests [18,19]. In some cases, capture can be expected to lead to less regulation, or less stringent regulation, than would be optimal. In other cases, business interests actually may support stringent regulation in order to impose costs on new competitors [20,21]. Risk regulation will sometimes include "grandfather" clauses that exempt existing uses or otherwise apply more stringent control requirements on new sources of risk, which can impose cost barriers to the entry of competitors [22,23].

Despite the real pressures business organizations can exert on the regulatory process, the expansive growth of regulation over the past half-century cannot be easily squared with regulatory capture. If industry controlled the process of making regulation, developed countries presumably would not have witnessed as expansive a growth in regulation addressing consumer protection, workplace safety, and environmental protection [24]. As economies have developed and educational levels have increased, members of the public today are less tolerant of a variety of risks than were previous generations [25]. Industry, no doubt, remains a politically important force in regulatory policymaking, but the increased political demand for regulation, generally, along with the development of well-organized labor, environmental, and consumer rights movements, has led to the creation of new regulatory agencies and greater levels of regulatory control over the last fifty years [26,27]. Competition across different jurisdictions may also sometimes create a "race to the top" in regulatory protection, as politicians in states or nations with less stringent regulations try to emulate jurisdictions with more stringent regulations in order to satisfy the demands of an increasingly risk averse public [28].

Risk regulation in advanced economies like the United States has evolved through an interplay between the legislature and

the bureaucracy. Legislatures pass laws that typically provide general frameworks for risk management, leaving responsibility for implementing those general frameworks to regulatory agencies. For example, the US Clean Air Act instructs the Environmental Protection Agency (EPA) to set ambient air quality standards at a level "requisite to protect the public health" with "an adequate margin of safety," but leaves it up to the EPA to decide what that actual level should be for a given air pollutant [29]. This delegation of regulatory authority from the legislature to the agency, especially under the terms of broad statutory language like that in the Clean Air Act example, create the conditions for a principal-agent problem, that is, the likelihood that regulators will stray from what the legislature intended [30,31]. In a democracy, who or what controls the unelected bureaucrats who establish risk standards?

Two complementary theories have emerged in the study of US risk regulation, one that emphasizes control by the President and one that emphasizes ongoing control by the Congress. Presidents exert influence over regulatory agencies by appointing the individuals who run them, overseeing their budget requests, and reviewing their most significant regulatory proposals [32]. Congress can also continue to exert influence over regulatory agencies by calling their administrators to testify and, more significantly, using the appropriations process as a carrot or stick [33,34]. Researchers find evidence that both Presidents and Congress affect the behavior of regulatory agencies [35–38].

Some scholars emphasize the role of administrative procedure in affecting what bureaucrats do and in holding them accountable to the elected branches of government. For example, the US Administrative Procedure Act of 1946 requires agencies to issue public notices of proposed rules and to give the public an opportunity to comment on these proposals before enacting them. Procedural requirements like these can help ensure that the same interest groups that supported an initial legislative delegation to an agency will have continued influence over that agency's actions [39,40]. Interest groups

can serve as surrogate monitors for the legislature, pulling a “fire alarm” when an agency seems to stray too far from the direction the Congress intended [34]. At its extreme, the theory of procedural control posits that Congress uses administrative procedures to “stack the deck” in ways that ensure agencies will carry out legislative preferences [39,40].

To date, the development of the theory of procedural control seems to have outpaced empirical support for the strong, stack-the-deck version of the theory [41–43]. But scholarly interest in administrative procedure has much deeper roots than just the recent theory of procedural control. Administrative law scholars have long posited that procedures could be used to advance a variety of desirable qualities in regulatory policy [44]. For example, they have favored opportunities for judicial review in order to encourage greater adherence to law and to promote better policy reasoning [45]. They have urged the use of innovations such as negotiated rulemaking to reduce regulatory conflict and speed up regulatory decision making [46]. Both legal scholars and economists have advocated procedural requirements for economic analyses of proposed rules as a means of promoting more efficient regulatory outcomes [47]. A growing empirical literature tests the claims advocates make for various forms of administrative procedure, often finding mixed or even negative results [48].

Whether or not procedures achieve substantial benefits in terms of improved decision making, some scholars have expressed concern that the simple accretion of procedural requirements imposed on agencies has come to hamper their ability to enact needed regulatory protections. Some have posited that a “paralysis by analysis” or “ossification” now grips the US regulatory process [49–51]. As with the purported benefits of regulatory procedure, these purported costs are subject to empirical investigation. To date, however, no systematic research has confirmed fears that procedures have placed any discernible barrier in the way of new regulation [48,52–55].

Comparative research on risk regulation across different developed economies provides another way of assessing the

effects that procedural or other institutional structures have on regulatory outcomes. The management of risk varies widely across jurisdictions [56]. Do the structures of regulatory policy making, or just more conventional political factors such as political parties or voter ideologies, explain differences in risk regulation across jurisdictions? Some countries in Europe have more “corporatist” regulatory structures that rely on formal collaboration between selected industry groups, labor representatives, and government officials; others like the United States are much more “pluralist” in allowing interest groups to compete against each other in an open, adversarial manner [57]. Although early work suggested that corporatist regulatory structures might lead to greater environmental controls [58], it appears that the stringency of environmental regulation is not related to institutional structures but rather (and not surprisingly) to the political strength of green and left-libertarian political parties [59].

SETTING RISK STANDARDS

Regulatory stringency is the core substantive issue at stake in setting risk management standards. Put simply, the issue has often been characterized by the question: How safe is safe? Answering this question requires making a normative decision about how much risk members of the public should confront in their lives. Setting risk standards “necessarily requires the use of value judgments on such issues as the acceptability of risk and the reasonableness of the costs of control” [60].

In making these value judgments about risk, decision makers can adhere to one of four basic normative principles or approaches [61]:

1. eliminate all risk—or at least all man-made risk (the zero-risk approach);
2. reduce risk to an acceptable level (the acceptable risk approach);
3. reduce risk until the cost of doing so reaches an unacceptable level (the feasibility approach); and

4. balance the benefits of risk reduction with the costs (the efficiency approach).

The zero-risk approach appeals to an intuitive notion of safety that implies complete freedom from any potential harm. Some laws appear to require this approach, such as the US Clean Air Act's provisions calling for standards that "protect the public health" with "an adequate margin of safety." The European Union's precautionary principle could also be viewed as indicative of a risk elimination approach [62].

In the context of setting environmental risk standards, a zero-risk approach would require standards set at levels below some exposure threshold at which adverse health effects occur. If, as seems increasingly the case for many chemicals, a given pollutant is nonthreshold in that some adverse effects arise from even the lowest levels of exposure, a zero-risk approach may require the complete elimination of the economic activity that relies upon or generates the chemical, even if doing so would create substantial, negative economic consequences. It is also possible, of course, that eliminating one kind of risk will only exacerbate another kind of risk. A standard that requires the removal of harmful substances from automobile brake pads may protect autoworkers and mechanics but could very well increase the risks from automobile accidents. In cases of such "risk-risk trade-offs" [63], the zero-risk approach can at best become a *minimize-risk* approach under which the regulator sets a standard at the nonzero level at which the marginal adverse effects of an economic activity equals the marginal adverse effects from reducing or controlling that activity.

Rather than seeking to eliminate or minimize risk, a second principled approach would reduce risk to an *acceptable* level. For example, no matter how much transportation safety regulation exists, anything short of banning airplane flights will always leave some residual risk of injuries and fatalities from air travel. A transportation safety regulator could, nevertheless, act to reduce risks to an acceptable, even if nonzero, level. In other contexts, regulators have also followed this approach. The US Occupational

Safety and Health Administration (OSHA) uses a benchmark mortality level of 1 in 1000 as the basis for its occupational health standards and the US EPA has sometimes deemed individual mortality risks below 1 in 10,000 to be acceptable [61].

An acceptable risk approach has its limitations. For one, an acceptable risk approach needs benchmarks not just for mortality risks as EPA and OSHA have used, but also for morbidity risks. A reason that agencies have not developed as clear a set of benchmarks for morbidity risks is that it is much harder to determine what those appropriate benchmarks should be. Regulators must also grapple with the choice between individual risk and population risk, as even a tiny individual risk could lead to a large total public health effect if a vast proportion of the population is exposed to a risk [61]. Determining what level should be deemed "acceptable" will most likely call for difficult value judgments; it is far from self-evident whether 1 in 1000 or 1 in 10,000 is the right level. Moreover, an acceptable risk approach disregards costs altogether, implying that regulators must act to reduce risks to an "acceptable" level even when the costs of doing so are disproportionately (and unacceptably) high. Correspondingly, the acceptable risk approach directs regulators to avoid reducing risks below the acceptable level, even when the costs of doing so would be *de minimus*.

A third approach—the feasibility principle—emphasizes costs in much the same way that the acceptable risk approach emphasizes benefits. The feasibility principle directs regulators to tighten the stringency of risk standards to the point at which the costs of complying with the standard reaches an unacceptable level. For example, the US Congress has directed OSHA to develop toxic exposure standards that will protect workers from harm "to the extent feasible"—that is, up to the point at which costs become unacceptable [64]. Just as regulating to achieve levels of acceptable risk disregards costs, regulating to avoid levels of unacceptable costs disregards the benefits of risk control. A risk standard might be infeasible in the sense that it would force the shutdown of a major industry, but if doing so

would save tens of thousands of lives, such economic disruption is almost surely worth it. The US phase-out of lead as an additive in gasoline seems a good example where high costs, even the significant contraction of a major industry, were clearly justified in order to secure significant public health benefits [65].

Cost-benefit balancing, the fourth principle for setting risk management standards, avoids the problems of the acceptable risk and unacceptable cost approaches [66]. By taking both costs and benefits into consideration, the balancing principle directs regulators to set risk standards at the socially efficient level, that is, the level that maximizes net benefits (i.e., benefits minus costs). If tightening a risk standard will generate high costs and deliver only few benefits, it should not be adopted. On the other hand, even if only a few benefits come from making a standard incrementally more stringent, doing so will be justified if the incremental costs are even lower than the incremental benefits. In the United States, the efficiency principle has not only been favored by economists [67], but has also been embedded in an executive order applied to regulatory agencies since the Reagan administration. The current order, Executive Order 12,866, requires agencies to “propose or adopt a new regulation only upon a reasoned determination that the benefits of the intended regulation justify its costs” [68].

Those economists and legal scholars who favor cost-benefit balancing do so because they believe it can achieve the most risk reduction for the resources devoted to meeting risk standards [66,67,69]. Currently, the estimated net benefits of risk regulation vary markedly across, and within, policy areas. Some regulations have been estimated to cost only in the tens of thousands of dollars per life saved; others have been estimated to cost billions of dollars for each life saved [70].

Despite the attraction of cost-benefit balancing, many scholars and political officials have resisted its widespread application. Applying this approach requires converting the costs and benefits of risk regulation into a common metric, typically a monetary one. The monetization of benefits generates objections, in particular when these benefits

involve the protection of human life [71,72]. Of course, even if benefits are not explicitly monetized, when regulators choose between policy alternatives with greater and lesser levels of risk control they are implicitly making value judgments about health and life. Additional value judgments must be made when the costs and benefits of control are not equally distributed, as frequently is the case.

Applying cost-benefit balancing also raises a series of other choices over how to estimate benefits and costs. One choice is whether to rely on estimates of how much individuals are willing to accept to forego risk reduction versus how much they are willing to pay to secure the same reduction. Although theoretically these two choices should lead to comparable amounts, willingness-to-accept amounts have sometimes been higher than willingness-to-pay amounts for equivalent risks [73]. In practice, economists typically have relied on willingness-to-pay amounts.

Another choice centers on the methods for obtaining value estimates, primarily for benefits that do not normally have market prices associated with them. Regulatory analysts can try to extrapolate using revealed preference methods, such as those that use the differences in wages in jobs with different risk profiles to extrapolate a monetized value of a statistical life [74]. Alternatively, analysts can rely on stated preference methods, such as contingent valuation surveys that ask individuals how much they would be willing to pay (or accept) for certain levels of risk reductions (or risk exposures) [74].

A final choice in applying the efficiency principle involves the discount rate used to place all monetary estimates into present value [75]. Not all costs and benefits occur at the same time; regulations addressing health risks with long latency periods will incur immediate costs but will deliver benefits only on a longer time horizon. The choice of what discount rate to use may affect the determination of whether a new risk standard will yield positive net benefits, as higher discount rates will tend to make long-term benefits smaller in present value terms [76].

DESIGNING RISK REGULATORY INSTRUMENTS

In addition to determining risk standards' stringency, regulators also must choose the form or design of risk regulation. Many environmental, health, and safety risk standards are designed to direct regulated firms to adopt specific means of risk control, such as by mandating the use of protective devices on machinery or the installation of specific pollution control techniques. Other risk standards impose an obligation on firms to meet a stated level of performance, such as when they prohibit pollution that exceeds specified emissions limits. Such performance standards provide firms with more flexibility as each firm can choose its own means of meeting the required level of performance [77]. But both means-specific and performance standards—sometimes referred together to as *command-and-control* regulation—treat all firms equally, requiring each firm either to adopt the same type of risk control measures or achieve the same level of risk control. Since the costs of risk control can vary across firms, a one-size-fits-all approach can result in excessive overall costs from risk regulation.

A more cost-effective way of achieving the same level of aggregate risk reduction would have firms with lower costs of control reduce risk more than firms with higher costs of control. For this reason, market-based regulatory instruments have been long advocated, and occasionally implemented, because they allow firms to achieve different levels of control. Market-based instruments include taxes, ideally set equal to the costs that risky activity imposes on society [78], and tradable permit systems [79,80]. With tradable permits, the regulator determines an overall level of aggregate risk (or a level of a proxy for that risk), issues individual output permits that add up to the desired aggregate level, and then allows firms to trade their individual permits with each other. In the environmental area where this approach has been most prominently used, tradable permits have been thought to be better suited for risks that arise from mixable pollutants than for those that arise

from exposure to highly toxic chemicals. The flexibility tradable permits afford regulated entities can lead to concentrated “hot spots” with higher levels of pollution, even if overall levels decline. For risk problems where some variation in risky outputs is acceptable—because it is the overall level of such outputs that matters—market-based instruments can lower costs. With regulatory instruments like tradable permits, firms can have an incentive to make even greater reductions in risky behavior so they can sell their excess credits. Economists have analyzed the conditions for deploying either taxes or tradable permits [81,82], and a body of research on market-based risk regulation has developed as governments have experimented with its use [83,84]. The US government has successfully deployed tradable permits both to phase out the use of lead additives in gasoline [65,85,86] as well as to reduce emissions of sulfur dioxide from coal-powered electric utilities [87].

To work effectively, market-based instruments require government regulators to monitor and measure outputs. But some risks—or precursors to risks—are quite difficult or costly to monitor. This may be because (i) they arise only from relatively low-probability events, (ii) the causal pathways to the risk are complex, or (iii) a monitoring technology does not readily exist. In such circumstances, regulators have sometimes responded by adopting management-based regulations, mandating that firms themselves identify the risks posed from their own operations and develop internal policies and procedures to manage those risks [88,89]. A well-known example is the application of Hazard Analysis and Critical Control Point (HACCP) requirements on food-processing facilities by governments around the world. Under HACCP, food processors are required to identify critical points where contamination could arise in their production processes, and then to develop their own measures for preventing such contamination from arising and ensuring that their employees carry out these measures [90]. Management-based regulation has been demonstrated to achieve reductions [91]; however, especially when it is used in

situations where governmental monitoring is difficult, management-based regulation can never be said to guarantee that firms will invest the resources needed to make socially optimal risk reductions [92,93].

Much the same can be said of other alternative regulatory responses. Governments sometimes impose information disclosure requirements, either providing consumers or the government information about the risks associated with their products or processes. Such information-based strategies have long been a staple of financial regulation, but they also have been used in recent years to address health and safety risks in a variety of areas [94,95]. Information disclosure appears more likely to prove effective when it actually can affect decisions by investors or customers, giving rise to other (nonregulatory) pressures for risk reduction.

The US Toxic Release Inventory (TRI) program, adopted in the late 1980s, requires certain companies to disclose their emissions of toxic chemicals [96]. Some researchers have suggested that the pressures activated by TRI-reporting led firms to reduce their toxic emissions by substantial amounts [97,98]. Of course, these studies have not adequately accounted for the contributions of more conventional regulation to this decline, which is important to consider given that nearly contemporaneous amendments to the Clean Air Act imposed new regulatory controls on the same hazardous air pollutants that would be reported under TRI. For this reason, TRI's unique impact on toxic emissions remains, "to date, unknown" (96, p. 242).

More research will be needed to assess the effectiveness of innovative regulatory designs like market-based instruments, management-based regulation, and information disclosure. Evaluation research can be conducted on the existing application of these designs to risk problems as well as on their use to address new forms of risk. Governments are only likely to continue to experiment with these and perhaps new forms of regulatory instruments altogether in the face of pressing or emerging areas of risk ranging from global climate change to nanotechnology. Empirical evaluation of these new regulatory strategies should aim

to compare the outcomes achieved under innovative policies with a realistic appraisal of more conventional forms of regulation [99]. Conventional regulation is certainly not immune from outcomes that are ineffectual or even counterproductive. Regulation of any kind can lead to adaptations in behavior that offset the risk reductions intended to be achieved through regulation. If drivers in cars with seat belts or airbags end up driving faster [100,101], or if parents are more likely to leave medications with child-resistant packaging in areas accessible to their small children [102], protective regulations will not reduce risk as much as their designers may intend and sometimes they may even create or exacerbate other kinds of risks.

CONCLUSION

Regulation provides a central means for government to manage the risks associated with today's global, industrialized economy. Markets themselves cannot adequately protect the public from hidden hazards or spillover harms. *Ex post* liability, while useful, does not always by itself provide a socially optimal level of risk control. As such, preventative risk regulation will be needed, and the core questions will remain about how stringent should such regulation be, and what form should such regulation take. Risk regulation research will continue to be needed to provide conceptual clarity to the normative basis for risk standards as well as to generate better empirical evidence on the effectiveness, efficiency, and equity of applying particular regulatory instruments under varied risk conditions.

THE $M/G/1$ QUEUE

ONNO J. BOXMA
Department of Mathematics,
Eindhoven University of
Technology, Eindhoven,
The Netherlands

A.K. Erlang's 1909 paper "The theory of probabilities and telephone conversations" [1] may be viewed as the birth of queueing theory. In the century following this publication, queueing theory has developed into a strong branch of both applied probability and stochastic operations research. Its development has, time and again, been fueled by new developments in communications, and it has also frequently been inspired by problems posed by production and computer networks. The sustained success of queueing theory is to a considerable extent due to the fact that there are a few very natural, basic, models which turn up all the time in new practical problems, but usually with new aspects or extensions which make it challenging to study them. These basic models are the Erlang loss model (see *The M/G/s/s Queue*), the Jackson network [see *Jackson Networks (Open and Closed)*] and the $M/G/1$ queue, which is the subject of the present contribution. They have been studied extensively, are very well understood, and are taught in courses all over the world. They have also served as testing grounds for new methods.

Accordingly, our contribution is also methodologically oriented; we shall discuss several methods to study key performance measures for the $M/G/1$ queue, like queue length, waiting and sojourn time, and busy period. There are other performance measures worthy of consideration. One example is the cycle maximum, that is, the maximum workload during a busy period. Methods for that quantity are discussed in Ref. 2.

We restrict ourselves to steady-state metrics, although the transient behavior of the $M/G/1$ queue is also an important topic.

THE $M/G/1$ MODEL

The $M/G/1$ queue is a single-server queue. Customers arrive at the service facility according to a Poisson process, with rate λ , requiring a particular amount of service. Let B_i denote the service requirement of the i th arriving customer. It is assumed that $B_1, B_2, \dots$ are independent, identically distributed (i.i.d.) random variables. In the sequel, B denotes a generic service requirement, and $\mathbb{E}[e^{-\omega B}]$ denotes its LST (Laplace–Stieltjes transform). If an arriving customer finds the server busy, then it joins the queue. The size of the waiting room is assumed to be infinite. The server serves customers in order of arrival (FCFS: first come first served), working at unit speed. Throughout the paper it is assumed that $\rho := \lambda \mathbb{E}[B] < 1$. This condition, which states that the mean offered amount of work per time unit is less than one, is necessary and sufficient for the existence of the steady-state distributions of the key performance measures.

There are numerous modifications and generalizations of the above-described basic $M/G/1$ model. We mention a few, giving one key reference for each:

- finite waiting room [3];
- customer impatience [4];
- server setup time for the first service in a busy period [5];
- server vacation at the end of a busy period [6];
- group arrivals and/or group service [7];
- workload-dependent service speed [8];
- several customer classes, but no priorities [9];
- several customer classes, with priorities (see [10]);
- polling models;
- matrix-geometric models. See, in particular, the books by Neuts [11,12], and the paper by Lucantoni [13] on the $BMAP/G/1$ queue, in which the Poisson

arrival process is generalized to a batch Markovian arrival process.

The text is organized as follows: The first section is devoted to the queue-length process, at various time epochs (arbitrary, arrival, and departure epochs). The waiting and sojourn time distributions are studied in the next section, followed by the section titled “The Busy Period.” In the last section we shall consider service disciplines other than FCFS.

QUEUE-LENGTH DISTRIBUTION

Let N^a , N^d , and N denote, respectively, the steady-state queue length (number in system) just before an arrival, just after a departure, and at an arbitrary epoch. PASTA (see **PASTA and Related Results**, [14]) implies that

$$N^a \stackrel{d}{=} N,$$

where $\stackrel{d}{=}$ denotes equality in distribution. Arguing that neither arrivals nor departures occur in groups, so that, in steady state, the number of customers increases from n to $n+1$ just as often as it decreases from $n+1$ to n , for $n = 0, 1, \dots$, it is seen that

$$N^a \stackrel{d}{=} N^d.$$

So to study N^a , N^d or N , it suffices to study just one of them. In a very influential paper, Kendall [15] has analyzed N^d . His fundamental observation was that the numbers of customers $N_1^d, N_2^d, \dots$ at successive departure epochs form a Markov chain, due to the memoryless property of the Poisson arrival process. Obviously, the number of customers at successive arrival epochs do *not* form a Markov chain, and neither is the process $\{N(t), t \geq 0\}$ of the number of customers at time t in general a continuous-time Markov process.

The following recursion holds:

$$\begin{aligned} N_{n+1}^d &= \max(0, N_n^d - 1) + A(B_{n+1}), \\ n &= 1, 2, \dots, \end{aligned} \quad (1)$$

where $A(B_{n+1})$ denotes the number of arrivals during the service time B_{n+1} . This recursion confirms that $\{N_n^d, n = 1, 2, \dots\}$ is a discrete-time Markov chain. Its transition probabilities $P_{ij} = \mathbb{P}(N_{n+1}^d = j | N_n^d = i)$ equal 0 if $j < i - 1$. Furthermore, defining the probability of having n arrivals during a service time

$$\alpha_n := \int_0^\infty e^{-\lambda t} \frac{(\lambda t)^n}{n!} d\mathbb{P}(B < t),$$

we have

$$\begin{aligned} P_{0j} &= \alpha_j, \quad j = 0, 1, \dots, \\ P_{ij} &= \alpha_{j-i+1}, \quad i = 1, 2, \dots, \quad j = 0, 1, \dots. \end{aligned}$$

The steady-state probabilities $d_n := \mathbb{P}(N^d = n)$ satisfy the following equation:

$$d_k = \sum_{j=0}^k d_{k+1-j} \alpha_j + d_0 \alpha_k, \quad k = 0, 1, \dots \quad (2)$$

Introducing the generating functions

$$D(z) := \sum_{k=0}^\infty d_k z^k = \mathbb{P}(N^d = k) z^k,$$

$$A(z) := \sum_{k=0}^\infty \alpha_k z^k = \mathbb{E}[e^{-\lambda(1-z)B}],$$

it is readily verified, exploiting the convolution form of Equation (2), that

$$D(z) = \frac{A(z)}{z} (D(z) - d_0) + A(z) d_0,$$

so

$$D(z) = \frac{d_0(1-z)A(z)}{A(z) - z} = \frac{d_0(1-z)\mathbb{E}[e^{-\lambda(1-z)B}]}{\mathbb{E}[e^{-\lambda(1-z)B}] - z}.$$

The normalizing condition $D(1) = 1$, or the observation that d_0 equals the probability $\mathbb{P}(N = 0)$ of an empty system, yields $d_0 = 1 - \rho$. Finally,

$$D(z) = \mathbb{E}[z^{N^d}] = \frac{(1-\rho)(1-z)\mathbb{E}[e^{-\lambda(1-z)B}]}{\mathbb{E}[e^{-\lambda(1-z)B}] - z}. \quad (3)$$

This formula is sometimes referred to as the *Pollaczek–Khintchine* formula. Differentiation w.r.t. z yields

$$\mathbb{E}[N^d] = D'(1) = \frac{\lambda^2 \mathbb{E}[B^2]}{2(1-\rho)} + \rho. \quad (4)$$

We once more remind the reader that the same results hold for N^a and N .

WAITING AND SOJOURN TIME DISTRIBUTION

In this section, we present several methods to derive the (LST of the) waiting and sojourn time distributions in the $M/G/1$ queue with FCFS discipline. It should be noted that, nowadays, there are very efficient numerical inversion procedures known for LSTs of probability distributions.

In the sequel, W and S denote a generic waiting and sojourn time; $S = W + B$.

Method 1 [The distributional form of Little's law]. The FCFS service order implies that the customers present immediately after a customer departure are precisely the customers which have arrived during the sojourn time of the departing customer. Hence,

$$\begin{aligned} \mathbb{E}[z^{N^d}] &= \sum_{k=0}^{\infty} z^k \int_{t=0}^{\infty} e^{-\lambda t} \frac{(\lambda t)^k}{k!} d\mathbb{P}(S < t) \\ &= \mathbb{E}[e^{-\lambda(1-z)S}], \end{aligned} \quad (5)$$

a relation sometimes referred to as the distributional form of Little's law; Little's law itself stating that $\mathbb{E}[N] = \lambda \mathbb{E}[S]$ (see **Little's Law and Related Results**). From Equations (3) and (5),

$$\mathbb{E}[e^{-\lambda(1-z)S}] = \frac{(1-\rho)(1-z)\mathbb{E}[e^{-\lambda(1-z)B}]}{\mathbb{E}[e^{-\lambda(1-z)B}] - z},$$

so

$$\mathbb{E}[e^{-\omega S}] = \frac{(1-\rho)\omega \mathbb{E}[e^{-\omega B}]}{\omega - \lambda + \lambda \mathbb{E}[e^{-\omega B}]}. \quad (6)$$

Observing that the sojourn time of a customer is the sum of its waiting time and

its service time, and that these waiting and service times are independent, it follows that

$$\mathbb{E}[e^{-\omega S}] = \mathbb{E}[e^{-\omega W}] \mathbb{E}[e^{-\omega B}],$$

and hence,

$$\mathbb{E}[e^{-\omega W}] = \frac{(1-\rho)\omega}{\omega - \lambda + \lambda \mathbb{E}[e^{-\omega B}]}. \quad (7)$$

This formula is also known as the *Pollaczek–Khintchine* formula.

The distributional form of Little's law implies that $\mathbb{E}[N^d] = \lambda \mathbb{E}[S]$, and also yields relations between higher moments of N^d and S . From Equation (4),

$$\mathbb{E}[S] = \frac{\lambda \mathbb{E}[B^2]}{2(1-\rho)} + \mathbb{E}[B], \quad (8)$$

$$\mathbb{E}[W] = \frac{\lambda \mathbb{E}[B^2]}{2(1-\rho)}. \quad (9)$$

Remark. The so-called *Mean Value Approach* provides an easy way to derive $\mathbb{E}[W]$ for the $M/G/1$ queue and for many of its variants and generalizations. It is based on the following observations: A newly arriving customer first has to wait for the *residual service time* of the customer in service (if any). It also has to wait during the service of all waiting customers. Denoting a generic residual service time by R , and the numbers of *waiting* customers at an arrival epoch and in steady state by N_w^a and N_w , respectively,

$$\mathbb{E}[W] = \rho \mathbb{E}[R] + \mathbb{E}[N_w^a] \mathbb{E}[B].$$

PASTA implies that $\mathbb{E}[N_w^a] = \mathbb{E}[N_w]$, and Little's law gives $\mathbb{E}[N_w] = \lambda \mathbb{E}[W]$.

Hence

$$\mathbb{E}[W] = \rho \mathbb{E}[R] + \rho \mathbb{E}[W],$$

so

$$\mathbb{E}[W] = \frac{\rho \mathbb{E}[R]}{1-\rho}.$$

R is the same as the asymptotic forward recurrence time of a renewal process with service times as interrenewal times. It follows from renewal theory that $\mathbb{E}[R] = \mathbb{E}[B^2]/(2\mathbb{E}[B])$, and Equation (9) follows. It is

interesting to observe that the mean waiting time is determined by the first two moments of the service-time distribution.

Method 2 [Level crossings]. In the seventies, Brill and Posner, and Cohen, independently developed a level crossing method (see the survey in Ref. 16), which is based on a balancing argument between up- and downcrossings of a particular queue length or workload level. In the case of the workload of the $M/G/1$ queue, the argument is as follows: Let $V(x)$ denote the distribution of the steady-state workload (amount of work) V in the $M/G/1$ queue (which by PASTA is in distribution equal to the waiting time), and let $v(x)$ denote its density. Equating the rates to cross any level $x > 0$ from below and from above, it is seen that

$$v(x) = \lambda \int_{0-}^x \mathbb{P}(B > x - y) dV(y), \quad x > 0. \quad (10)$$

Note that $V(x) = V(0) + \int_0^x v(y) dy$, take LSTs on both sides of Equation (10), and exploit the fact that the LST of a convolution is the product of the LSTs of the individual terms:

$$\mathbb{E}[e^{-\omega V}] - V(0) = \lambda \mathbb{E}[e^{-\omega V}] \frac{1 - \mathbb{E}[e^{-\omega B}]}{\omega}. \quad (11)$$

Remark. It should be noted that $\frac{\mathbb{P}(B > z)}{\mathbb{E}[B]}$ is the density of the residual part R of the service time B , and that its Laplace transform equals $\frac{1 - \mathbb{E}[e^{-\omega B}]}{\omega \mathbb{E}[B]}$. It follows from Equation (11) that

$$\mathbb{E}[e^{-\omega V}] = \frac{V(0)}{1 - \rho \mathbb{E}[e^{-\omega R}]}. \quad (12)$$

Taking $\omega = 0$ yields the expected result that the probability of an idle server equals $V(0) = 1 - \rho$. PASTA implies that V and W , the workload as seen by an arriving customer, have the same distribution. Hence,

$$\mathbb{E}[e^{-\omega W}] = \mathbb{E}[e^{-\omega V}] = \frac{1 - \rho}{1 - \rho \mathbb{E}[e^{-\omega R}]}. \quad (13)$$

It is easily verified that this agrees with Equation (7).

Remark. As observed by Doshi [16], the same level-crossing method readily reveals that, in the $M/G/1$ queue with server vacations, a decomposition result holds: the workload is equal in distribution to the sum of two independent quantities, one being the workload in the model without vacations. See Ref. 17 for other $M/G/1$ decomposition results, and Ref. 18 for a workload decomposition in polling models.

Remark. A powerful tool which is related to level crossings is the Rate of Conservation Law (RCL); it is surveyed by Miyazawa [19].

Remark. An attractive feature of the representation (Eq. 13) is that inversion of the LST is straightforward:

$$\mathbb{P}(W < x) = (1 - \rho) \sum_{n=0}^{\infty} \rho^n \mathbb{P}(R_1 + \dots + R_n < x), \quad x > 0, \quad (14)$$

where $R_1, \dots, R_n$ denote n i.i.d. residual service times. See Ref. 20 for an interesting and elegant interpretation of this formula, exploiting work conservation (see **Conservation Laws and Related Applications**): the workloads under FCFS and under the LCFS-PR (last come first served preemptive resume) service discipline have the same distribution. Furthermore, the steady-state number of customers in the $M/G/1$ LCFS-PR queue is geometrically distributed with parameter ρ (see Ref. 21 for an elegant argument) and, as argued in Ref. 20, the residual service times of all customers present are i.i.d. copies of R .

Method 3 [Lindley's recursion]. We briefly outline a third method to derive Equation (7). The following relation, known as *Lindley's recursion*, holds between the waiting times W_n and W_{n+1} of the n th and

$(n + 1)$ st customers in a $GI/G/1$ FCFS queue:

$$W_{n+1} = [W_n + B_n - A_{n+1}]^+, \quad n = 1, 2, \dots, \quad (15)$$

where A_{n+1} denotes the interarrival time between the n th and $(n + 1)$ st customers and $[x]^+ = \max(0, x)$. Cohen (3, Section II.4.5) uses this recursion relation to determine the transient behavior of the waiting time in the $M/G/1$ queue. Below, we again restrict ourselves to the steady-state waiting-time behavior, rederiving Equation (7). Denoting by A a generic interarrival time, and by $(\cdot)$ an indicator function, we can write for the steady-state waiting-time LST in the $M/G/1$ case:

$$\begin{aligned} \mathbb{E}[e^{-\omega W}] &= \mathbb{E}[e^{-\omega[W+B-A]^+}] \\ &= \mathbb{E}[e^{-\omega[W+B-A]^+} (W+B \geq A)] \\ &\quad + \mathbb{E}[e^{-\omega[W+B-A]^+} (W+B < A)] \\ &= \mathbb{E}[e^{-\omega(W+B-A)} (W+B \geq A)] \\ &\quad + \mathbb{P}(W+B < A) \\ &= \mathbb{E}[e^{-\omega(W+B-A)}] - \mathbb{E}[e^{-\omega(W+B-A)} \\ &\quad \times (W+B < A)] + \mathbb{P}(W+B < A) \\ &= \mathbb{E}[e^{-\omega W}] \mathbb{E}[e^{-\omega B}] \frac{\lambda}{\lambda - \omega} \\ &\quad - \mathbb{P}(W+B < A) \left[\frac{\lambda}{\lambda - \omega} - 1 \right], \quad (16) \end{aligned}$$

where in the last step we have used that $A - W - B$, when positive, is $\exp(\lambda)$ distributed. After some rewriting, we obtain

$$\mathbb{E}[e^{-\omega W}] = \frac{\mathbb{P}(W+B < A)\omega}{\omega - \lambda + \lambda \mathbb{E}[e^{-\omega B}]}. \quad (17)$$

The normalizing condition implies that $\mathbb{P}(W+B < A) = 1 - \rho$, which makes sense as $\mathbb{P}(W+B < A) = \mathbb{P}([W+B-A]^+ = 0) = \mathbb{P}(W=0)$. We thus recover Equation (7).

Finally, we mention three other elegant derivations of Equation (7): a combinatorial method, developed by Takács [22], starting from a generalization of the classical ballot theorem; a derivation that exploits the regenerative structure of the waiting-time process

w.r.t. a busy period ([23], pp. 20–22); and one based on the Kella–Whitt martingale [24].

THE BUSY PERIOD

The following beautiful argument for deriving the joint distribution of the length of a busy period, P , and the number of customers served in it, K , is presented in Takács [25]. Consider the service time B_1 of the customer who starts a busy period by entering an empty system. Condition on the number of arrivals $A(B_1)$ during that first service time. If $A(B_1) = 0$, then $P = B_1$. Else, temporarily remove $A(B_1) - 1$ customers from the system at the end of B_1 . Serve the remaining customer and subsequent new arrivals until the busy period initiated by that customer ends. Then take the second removed customer into service, etc., until all $A(B_1)$ customers and their busy periods have been served. Thus P consists of B_1 , and of $A(B_1)$ sub-busy periods:

$$\begin{aligned} P &= B_1 + P_1 + \dots + P_{A(B_1)}, \\ K &= 1 + K_1 + \dots + K_{A(B_1)}. \end{aligned}$$

Since the order of arriving customers is irrelevant for the length of the busy period (we could, for example, serve LCFS, first taking the *last* removed customer into service), and since the joint distribution of the length of any sub-busy period and the number served in it is the same as the joint distribution of the whole busy period and the number served in it, we can write

$$\begin{aligned} \mathbb{E}[r^K e^{-\omega P}] &= r \int_{t=0}^{\infty} e^{-\omega t} \sum_{k=0}^{\infty} e^{-\lambda t} \frac{(\lambda t)^k}{k!} \\ &\quad \prod_{i=1}^k \mathbb{E}[r^{K_i} e^{-\omega P_i}] d\mathbb{P}(B_1 < t) \\ &= r \int_{t=0}^{\infty} e^{-\omega t} \sum_{k=0}^{\infty} e^{-\lambda t} \frac{(\lambda t)^k}{k!} \\ &\quad \times (\mathbb{E}[r^K e^{-\omega P}])^k d\mathbb{P}(B_1 < t) \\ &= r \mathbb{E}[e^{-(\omega + \lambda - \lambda \mathbb{E}[r^K e^{-\omega P}])B}]. \quad (18) \end{aligned}$$

It can be shown that $\mathbb{E}[r^K e^{-\omega P}]$ is the smallest zero, inside the unit circle, of the function $z - r \mathbb{E}[e^{-(\omega + \lambda(1-z))B}]$. In particular, it can

be shown that $\mathbb{E}[e^{-\omega P}]$ is the smallest zero, inside the unit circle, of the function $z - \mathbb{E}[e^{-(\omega + \lambda(1-z))B}]$.

Inversion of Equation (18) turns out to be possible [3, p. 250]:

$$\mathbb{P}(K = k, P < t) = \int_0^t e^{-\lambda u} \frac{(\lambda u)^{k-1}}{k!} d\mathbb{P}(B_1 + \dots + B_k < u). \quad (19)$$

We refer to Takács [22] for a combinatorial method of obtaining the busy-period distribution, which directly yields Equation (19).

The mean busy period is obtained via differentiation of Equation (18) (or via the simple balancing argument $\mathbb{E}[P] = \mathbb{E}[B] + \rho \mathbb{E}[P]$):

$$\mathbb{E}[P] = \frac{\mathbb{E}[B]}{1 - \rho}. \quad (20)$$

Notice that the mean busy period is only determined by the service-time distribution via its first moment.

OTHER SERVICE DISCIPLINES

So far we have restricted ourselves to the FCFS service discipline. An abundance of service disciplines has been studied for the $M/G/1$ queue. Arguably, the most important alternatives to FCFS are SRPT (shortest remaining processing time first), LCFS-PR, which was already briefly considered in the section titled “Waiting and Sojourn Time Distribution,” and PS (processor sharing).

SRPT. Under SRPT, the server always serves the customer with the shortest remaining service requirement. Intuitively, this leads to the smallest number of customers in the system, and hence in particular also to the smallest mean queue length and, by Little, to the smallest mean waiting time. Schrage [26] has indeed proven this optimality result. The queue-length distribution for $M/G/1$ SRPT is obtained by Schassberger [27], and the waiting and sojourn time distributions by Schrage and Miller [28].

LCFS-PR. Under LCFS-PR, the last arriving customer is immediately taken into service. The customer in service is temporarily set aside, and its preempted service is resumed as soon as that last arriving customer, as well as all customers which arrived during its service, during their service, and so on, have been served. LCFS-PR is particularly interesting from a theoretical point of view. Firstly, the $M/G/1$ LCFS-PR queue belongs to the class of *symmetric* queues [29, Section 3.3]. Nodes with such a discipline in a network of queues with Markovian routing allow for a joint queue-length distribution that has a product form. The steady-state queue-length distribution in an $M/G/1$ LCFS-PR queue is geometric with parameter ρ , the traffic load. Secondly, LCFS-PR has a kind of memoryless property: at an arrival epoch, the number of customers or the amount of work already present plays no role at all during the time that the arriving customer is present. This has been exploited in various studies, like those in Ref. 17 and 21. A special consequence is also that the sojourn time in $M/G/1$ LCFS-PR is in distribution equal to the busy period.

PS. Under PS, all customers present in the system are simultaneously being served, each receiving an equal fraction of the server capacity. PS was introduced by Kleinrock as the limit of the round-robin discipline in computer processors, where jobs receive a very small slice of service and subsequently return to the end of the queue, this process repeating itself until the job has been completely processed. More recently, PS has found new applications in representing bandwidth-sharing policies in modern communication networks like the Internet. The following interesting fairness property holds in $M/G/1$ PS: the mean sojourn time of a customer with service requirement x is $\frac{x}{1-\rho}$; that is, linear in x .

Like LCFS-PR, PS is a symmetric discipline which plays a key role in product form networks. Like LCFS-PR, the queue-length distribution in $M/G/1$ PS is geometric with parameter ρ . The sojourn time distribution is more complicated than for FCFS and LCFS-PR, though. It was independently derived by Yashkov, Ott and Schassberger. We refer to Ref. 30 for an interesting survey of processor-sharing models.

THE $M/G/s$ QUEUE

TOSHIKAZU KIMURA
Graduate School of Economics
and Business Administration,
Hokkaido University,
Sapporo, Japan

Multiserver queues have been important models for evaluating the performance of a variety of service systems in the fields of computer, communication, transportation, and manufacturing. In particular, systems with Poisson inputs have been of general interest in these fields, due to intuitive interpretation and analytical tractability of the Poisson process. We consider the standard $M/G/s/s+r$ queue with $s(\geq 1)$ homogeneous servers in parallel, $r(\geq 0)$ extra waiting spaces, and the FCFS (first-come first-served) discipline. Customers are arriving at the system according to a Poisson process and are lost if they arrive when all s servers are busy and all r waiting spaces are full, namely they leave without receiving services and without affecting future arrivals. Their service times are iid (independent and identically distributed) random variables with a common cdf (cumulative distribution function) and independent of the arrival process. The $M/G/s/s+r$ queue is relevant to other single-station queues: It coincides with the $M/G/s/s$ queue if $r=0$ (see **The $M/G/s/s$ Queue**) and the $M/G/\infty$ queue if $s=\infty$ (see **The $M/G/\infty$ Queue** and **The $M/M/\infty$ Queue**). Also, it is a generalization of the $M/M/s$, $M/M/s/c$ and $M/G/1$ queues (see **The $M/M/s$ Queue**). In this article, we primarily focus on the case of unlimited waiting spaces ($r=\infty$), namely, the $M/G/s$ queue, with emphasis on its classical results because some recent results related to the $M/G/s$ queue are separately reviewed, for example, in the articles titled **Large Deviations in Queueing Systems** for large deviations, and **Markov Chains of the $M/G/1$ -Type** for the $M/G/1$ -type Markov chain analysis, in this encyclopedia.

EXACT RESULTS

Formulation

Let $N(t)$ denote the number of customers either waiting or being served at time t (≥ 0) in the $M/G/s$ queue. For the $M/G/1$ case, the instants of service completion are points of regeneration of the process $\{N(t); t \geq 0\}$. However, such an embedded Markov chain technique is of no use for the $M/G/s$ queue, since it is difficult to follow through successive customers due to the fact that they enter the queue in one order but leave the servers in another. Unlike the $M/M/s$ queue, the probability of service completion of a customer depends on its *age* at that instant. The dependence on the age of customers must be taken into account to analyze the $M/G/s$ queue, which can be realized by the method of inclusion of supplementary variables [1]; see Pollaczek [2] for an earlier analysis without using the supplementary variables. The supplementary variables are defined as either the elapsed or remaining service times of customers in service at arbitrary time. If we denote these supplementary variables at time t by $V_1(t), \dots, V_s(t)$, then the vector-valued process $\{(N(t), V_1(t), \dots, V_s(t)); t \geq 0\}$ becomes Markovian, and hence a set of equations for the state probabilities can be formulated by using transformations such as the generating function with respect to the discrete state $N(\cdot)$ and the multiple Laplace transform with respect to the vector $(t, V_1, \dots, V_s)$; see Syski [3, pp. 262–268] for details. See also Hokstad [4, pp. 512–515] for the formulation in equilibrium.

The equations for the transformed state probabilities is too involved to obtain its solution, even if the queue is in steady state. Using the equations, however, we can prove the PASTA property [5] that the steady-state probability of $N(\cdot)$ at an arrival epoch is equal to $P_j = P(N=j)$ ($j \geq 0$), the steady-state probability at an arbitrary epoch, where N is a generic random variable for $N(\cdot)$ at

arbitrary time in equilibrium [4, p. 514]. See also the article titled **PASTA and Related Results** in this encyclopedia for results related to PASTA.

For further analysis, we use the following notation: let λ denote the arrival rate of customers and let G denote the service-time cdf with mean μ and the squared coefficient of variation (variance divided by the square of the mean) c^2 . Let $\rho = \lambda/s\mu$ be the traffic intensity and assume that the system is stable and in steady state, that is $\rho < 1$ (for $r = \infty$) [6]. In addition, let $Q = \max(N - s, 0)$ be the number of customers in queue at an arbitrary epoch (excluding any customer in service) and let W be the waiting time of an arbitrary customer before beginning his/her service. For the $M/G/s$ queue, it has been known that the number of customers who arrived during the waiting time W has the same distribution as the queue length Q [7]. Specifically, between Q and W , we have the relation

$$E[z^Q] = E[e^{-\lambda(1-z)W}], \quad |z| \leq 1. \quad (1)$$

When necessary, we will express a quantity as a function of the service-time cdf G , for example $W \equiv W(G)$, $P_j \equiv P_j(G)$, and so on.

Asymptotic Properties

The exact formulation is analytically intractable, but we can obtain asymptotic properties of characteristic quantities of the $M/G/s$ queue in heavy or light traffic, which would be useful for generating accurate approximations. In heavy traffic when ρ is less than, but close to unity, the waiting time W approximately has a negative exponential distribution given by

$$P(W(G) \leq x) \approx 1 - \exp\left\{-\frac{2\lambda(1-\rho)}{1+\rho^2c^2}\right\}, \quad x \geq 0,$$

from which we obtain

$$\lim_{\rho \rightarrow 1} (1-\rho)EW(G) = \frac{1+c^2}{2s\mu}; \quad (2)$$

see K  llerstr  m [8]. In light traffic, on the contrary, Burman and Smith [9, Corollary

3.3] obtained

$$\lim_{\lambda \rightarrow 0} E[W(G) | W(G) > 0] = \int_0^\infty \{1 - G_e(t)\}^s dt \equiv a(s),$$

where G_e is the stationary-excess cdf associated with G , that is,

$$G_e(t) = \mu \int_0^t \{1 - G(u)\} du, \quad t \geq 0,$$

and hence

$$\lim_{\rho \rightarrow 0} \frac{EW(G)}{EW(M)} = s\mu a(s), \quad (3)$$

using the asymptotic property that $P(W(G) > 0) \approx s\mu EW(M)$ as $\lambda \rightarrow 0$; see Whitt [10] and Wang and Wolff [11] for related results.

To analyze asymptotic properties in these extreme cases in a unified way, we introduce a normalized quantity $R(G) = EW(G)/EW(M)$ as a bivariate function of s and ρ . Then, the heavy and light traffic limits in Equations (2) and (3) can be considered as the boundary values of $R(G)$ at $\rho \rightarrow 0$ and $\rho \rightarrow 1$, respectively; that is,

$$\begin{aligned} \lim_{\rho \rightarrow 1} R(G) &= \frac{1}{2}(1+c^2) \quad \text{and} \\ \lim_{\rho \rightarrow 0} R(G) &= s\mu a(s). \end{aligned} \quad (4)$$

From the exact results for the $M/G/1$ and $M/G/\infty$ queues, we have the boundary values of $R(G)$ at $s = 1$ and $s \rightarrow \infty$, which are respectively given by

$$\lim_{s \rightarrow 1} R(G) = \frac{1}{2}(1+c^2) \quad \text{and} \quad \lim_{s \rightarrow \infty} R(G) = 1. \quad (5)$$

APPROXIMATE RESULTS

To deal with the analytical difficulty, a number of approximations have been developed for characteristic quantities in the $M/G/s$ queue; see Ovuworie [12] and Kimura [13] for bibliographies. According to Miyazawa [14], the methods of generating approximations can be classified into two categories: one is to obtain approximations by presuming

a parametric formula theoretically or intuitively. The parameters included are chosen to be consistent with known exact results. This method often generates simple approximations for mean quantities, being suited for quick engineering purposes. The other is to obtain approximations by solving either exact or approximate equations for the quantities using some additional assumptions or hypotheses. This method is particularly useful when we develop approximations for the queue length distribution, for which intuitive inference is difficult. We review previous approximations from the view point of this classification.

Of course, this classification is *not* everything to approximations for the $M/G/s$ queue. For example, the method of diffusion approximation has been applied to the $M/G/s$ queue and its extensions; see Kimura [15–17], Yao [18], Whitt [19] and the references therein. The entropy maximization approach can be also applied to analyzing the $M/G/s$ queue [20,21]. In addition, Whitt [22] and Choi *et al.* [23] developed and evaluated heuristic two-moment approximations for general multiserver queues.

Mean Waiting Time

The development of approximations for the mean of queue length or waiting time has a history longer than that of their distributions. Due to Little's law, there is no essential difference between these two mean quantities. Hence, we primarily focus on the mean waiting time $EW(G)$ for the $M/G/s$ queue. An early and typical approximation for $EW(G)$ is traced back to the work of Lee and Longton [24], which is $EW(G) \approx EW^{(L)}(G)$ with

$$EW^{(L)}(G) = \frac{1}{2}(1 + c^2)EW(M), \quad (6)$$

where $EW(M)$ is the mean waiting time of the associated $M/M/s$ queue given by

$$EW(M) = \frac{(s\rho)^s}{s!s\mu(1-\rho)^2}P_0(M),$$

with the empty probability

$$P_0(M) = \left[\sum_{j=0}^{s-1} \frac{(s\rho)^j}{j!} + \frac{(s\rho)^s}{s!} \frac{1}{1-\rho} \right]^{-1}.$$

The formula (6) came from the consistency with both, the exact result for the $M/M/s$ queue and the cases $s = 1$ and $\rho \rightarrow 1$. Another typical approximation formula in this category is $EW^{(P)}(G)$ defined as

$$EW^{(P)}(G) = c^2EW(M) + (1 - c^2)EW(D), \quad (7)$$

where $EW(D)$ is the mean waiting time of the associated $M/D/s$ queue. The formula (7) is based on a simple idea of interpolating the exact results for the $M/M/s$ and $M/D/s$ queues, and is consistent with the cases $s = 1$, $s \rightarrow \infty$, and $\rho \rightarrow 1$; see Cosmetatos [25] and Kimura [26–28] for details of *system interpolations*. Due to the simplicity of its idea, it is difficult to identify the original citation of the formula (7). Actually, the formula (7) has often appeared in the literature [13, p. 353]. Since the formula (7) is sometimes called *Page's approximation* [29] therein, we attached his initial to the formula.

The formulas (6) and (7), being classified as the first category, can be interpreted as approximations for the normalized quantity $R(G)$, that is $R(G) \approx \frac{1}{2}(1 + c^2)$ for Equation (6) and $R(G) \approx c^2 + (1 - c^2)R(D)$ for Equation (7), where $R(D)$ is the associated quantity for the $M/D/s$ case. Most approximations for $EW(G)$ also can be regarded as those for $R(G)$, at least when they are consistent with $EW(M)$.

Table 1 summarizes those approximations from the point of view of approximating $R(G)$, together with a checklist of the consistency with the exact boundary values in Equations (4) and (5). In Table 1, two approximations specific to $R(D)$ are also added due to the difficulty of calculation. Cosmetatos' approximation [30, Equation (1)] $R^{(C)}(D)$ is sufficiently accurate for computing $EW(D)$ itself, but it has two serious defects such that $\lim_{s \rightarrow \infty} R^{(C)}(D) = \infty$ and $\lim_{\rho \rightarrow 0} R^{(C)}(D) = \infty$. (Note that $\lim_{s \rightarrow \infty} R(D) = 1$ and $\lim_{\rho \rightarrow 0} R(D) = s/(s+1) < 1$.) Hence, if one needs an approximation for $R(D)$ as a part of a certain approximation such as $R^{(B)}(G)$, it is highly recommended that Kimura's approximation is used [13, Equation (4.29)] $R^{(K)}(D)$, which is consistent with all of the exact boundary values; see Kimura [31] for a more sophisticated and accurate approximation.

Table 1. Summary of the approximations for $R(G)$ and $R(D)$

Queue Length Distribution

Elaborate approximations for $\{P_j(G)\}$ have been developed so far by several researchers. Among them, Hokstad [4], Tijms *et al.* [32] and Miyazawa [14] have made significant contributions to approximations in the second category.

Hokstad [4] adopted the method of supplementary variables to obtain the approximation

$$P_j^{(H)} = \begin{cases} \frac{(s\rho)^j}{j!} P_0(M), & j = 0, \dots, s-1, \\ (h_{j-s} - h_{j-s-1}) P_{s-1}^{(H)}, & j \geq s, \end{cases} \quad (8)$$

where $h_{-1} = 1$ and $\{h_j; j \geq 0\}$ is given by the generating function

$$H(z) \equiv \sum_{j=0}^{\infty} h_j z^j = \frac{1}{\gamma(z) - z} \quad \text{with} \\ \gamma(z) = \int_0^\infty e^{-\lambda(1-z)t/s} dG(t),$$

for $|z| \leq 1$. The sequence $\{h_j\}$ can be easily computed by numerical inversion of the generating function [35].

Tijms *et al.* [32] used a regenerative approach to derive three different approximations, namely, Cases A through C, of which Case B agrees with Hokstad's approximation. The numerical scheme for computing Case C requires much more work than those for Cases A and B, so that Case C is mainly of value for approximating $\{P_j\}$ for the $M/D/s$ queue. Their representative approximation of Case A, $\{P_j^{(T)}\}$, can be obtained by recursively solving the infinite system of linear equations

$$P_j^{(T)} = \begin{cases} \frac{(s\rho)^j}{j!} P_0(M), & j = 0, \dots, s-1, \\ \lambda \alpha_{j-s} P_{s-1}^{(T)} + \lambda \sum_{k=s}^j \beta_{j-k} P_k^{(T)}, & j \geq s, \end{cases} \quad (9)$$

together with the normalizing condition $\sum_{j=0}^{\infty} P_j^{(T)} = 1$, where for $j \geq 0$,

$$\alpha_j = \int_0^\infty \{1 - G_e(t)\}^{s-1} \{1 - G(t)\} e^{-\lambda t} \frac{(\lambda t)^j}{j!} dt, \\ \beta_j = \int_0^\infty \{1 - G(st)\} e^{-\lambda t} \frac{(\lambda t)^j}{j!} dt.$$

The recursion scheme for solving Equation (9) with integral-form coefficients is actually too burdensome. It is necessary to reduce the infinite system of linear equations to a relatively small system of linear equations, for example by using the geometric tail approach discussed in Tijms [36, pp. 298–299]. An alternative expression for $\{P_j^{(T)}\}$ has been obtained by Kimura [37, Proposition 3.2] as a special case of his results for the finite capacity $M/G/s$ queue, which is

$$P_j^{(T)} = \begin{cases} \frac{(s\rho)^j}{j!} P_0(M), & j = 0, \dots, s-1, \\ (t_{j-s} - t_{j-s-1}) P_{s-1}^{(T)}, & j \geq s, \end{cases} \quad (10)$$

where $t_{-1} = 0$ and $\{t_j; j \geq 0\}$ is given by the generating function

$$T(z) \equiv \sum_{j=0}^{\infty} t_j z^j = \frac{\lambda}{\gamma(z) - z} \int_0^{\infty} \{1 - G_e(t)\}^{s-1} \{1 - G(t)\} e^{-\lambda(1-z)t} dt,$$

for $|z| \leq 1$. The numerical inversion method for $T(z)$ would be a highly effective means for computing $\{P_j^{(T)}\}$ in common with $\{P_j^{(H)}\}$.

Miyazawa [14] aimed for affording theoretical insight into the approximations for $\{P_j(G)\}$ in the second category, giving a unified view of the previously established approximations. Using a rate conservation law [38], he provided reasonable interpretations of assumptions used in the approximations of Nozaki and Ross [39], Hokstad [4], and Case A of Tijms *et al.* [32]. In addition, he derived three new approximations for $\{P_j(G)\}$, Cases 1 through 3, in terms of generating functions. Among them, Case 2 has performance similar to Case A of Tijms *et al.* [32]. Case 3 is more complicated than Cases 1 and 2, and Case 1 is less accurate than Cases 2 and 3. Hence, the approximation of Case 2 would be of practical use.

In Table 1, we also give the approximations for $R(G)$ and $R(D)$ in the second category. From Table 1, we see that these approximations for $R(G)$ are *not* consistent with the asymptotic property as $s \rightarrow \infty$. However, this defect does not matter much for

practical purposes; see Ma and Mark [40] for a heuristic modification of $\{P_j^{(T)}\}$ for large s .

There are a few approximations for $\{P_j(G)\}$ in the first category. Based on the expression for $\{P_j(M)\}$, Kimura [41] suggested the geometric approximation

$$P_j^{(K)} = \begin{cases} \frac{(s\rho)^j}{j!} P_0(M), & j = 0, \dots, s-1, \\ C(s, \rho)(1-\eta)\eta^{j-s}, & j \geq s, \end{cases} \quad (11)$$

where $C(s, \rho)$ is the Erlang C formula of the associated $M/M/s$ queue; that is,

$$C(s, \rho) = \frac{(s\rho)^s}{s!(1-\rho)} P_0(M),$$

and η is a decay parameter. To obtain an appropriate approximation of the decay parameter η for the $M/G/s$ queue, Kimura [41] used a moment-matching with respect to $EW(G)$, obtaining

$$\eta = \frac{\rho R(G)}{1 - \rho + \rho R(G)}.$$

Clearly, the geometric approximation (Eq. 11) is exact for the $M/M/s$ case where $\eta = \rho$. It can be interpreted to view the $M/G/s$ queue as a system alternating between the associated $M/G/1$ and $M/G/\infty$ queues. This idea has been widely used such as in Hokstad [4], Tijms *et al.* [32], Newell [42], and Shore [43].

The delay probability is defined by $P(W(G) > 0) = \sum_{j=s}^{\infty} P_j(G)$ due to PASTA. From Equations (8), (9), and (11), these approximations give the Erlang delay probability approximation $P(W(G) > 0) \approx C(s, \rho)$, which has been known to usually be a good approximation for general service-time distributions. For large s , this approximation is certainly justified by the insensitive property of $M/G/\infty$ queue (see **The M/G/ ∞ Queue**). See also Miyazawa [14] and Kimura [44] for alternative approximations. To obtain the waiting time distribution $P(W(G) \leq t)$ ($t \geq 0$), we can apply the distributional Little's law in Equation (1) to each of the approximations for $\{P_j(G)\}$ in Hokstad [4, Equation (26)], van Hoorn and Tijms [45, Equation (5)] and Kimura [13, Equation (5.12)].

Optimal Buffer Design

In computer and communication systems, there are many important design issues that can be modeled by multiserver queues. A useful model for buffer capacity design in these systems is the $M/G/s/s+r$ queue. A buffer design problem is to find the smallest buffer capacity such that the proportion of lost customers (i.e., messages, transactions, etc.) is below an acceptable level. To obtain a concise expression for the optimal buffer size, we need an explicit formula for the loss probability, which is given by P_{s+r} due to PASTA. Approximations for $\{P_j(G)\}$ for the $M/G/s/s+r$ queue have been also proposed by Hokstad [4], Tijms and van Hoorn [46], Miyazawa [14], and Kimura [41] as extensions of their formulas for the $M/G/s$ queue; see Kimura [37] for some equivalence relations in those formulas. Among them, Miyazawa [14] and Kimura [41] obtained explicit approximation formulas for the loss probability. Based on these two explicit formulas, Kimura [47] obtained an alternative expression of the loss probability for $\rho \leq 1$, which is

$$P_{s+r}^{(K)} = \begin{cases} \frac{(1-\rho)\xi^r B(s, \rho)}{1 - \rho + \rho(1 - \xi^r)B(s, \rho)}, & \rho < 1, \\ \frac{B(s, 1)}{1 + \frac{2r}{1+c^2}B(s, 1)}, & \rho = 1, \end{cases} \quad (12)$$

where $B(s, \rho)$ is the Erlang B formula of the associated $M/G/s/s$ queue, that is

$$B(s, \rho) = \frac{(s\rho)^s}{s!} \bigg/ \sum_{j=0}^s \frac{(s\rho)^j}{j!},$$

and ξ is the exact rate of decay in the tail of $\{P_j(G)\}$ for the $M/G/s$ queue [48], which is defined by $\xi = \zeta^{-1}$ with the smallest positive root ζ of the equation $z = \gamma(z)$.

We can say that the buffer design problem is to find the smallest integer $r \geq 0$ for which $P_{s+r} \leq \epsilon$ for any acceptance level $\epsilon \in (0, 1)$. Since there exists a lower bound such that $P_{s+r} \geq 1 - \rho^{-1}$ when $\rho > 1$ [49, 50], there is no optimal value of r if $\epsilon \leq 1 - \rho^{-1}$ or, equivalently, if $\rho \geq 1/(1 - \epsilon) > 1$. Hence, for $\rho \leq 1$, there always exists the optimal

value of r for any $\epsilon \in (0, 1)$. For a given acceptance level ϵ , we define the optimal buffer size by $r_\epsilon \equiv r_\epsilon(G) = \min\{r \geq 0 \mid P_{s+r} \leq \epsilon\}$. If the acceptance level is more generous than the loss probability in the associated $M/G/s/s$ queue, it is not necessary to have extra buffer spaces. Hence, we immediately have $r_\epsilon(G) = 0$ if $\epsilon \geq B(s, \rho)$. From Equation (12), Kimura [47] proved that the optimal buffer size r_ϵ for $\epsilon \in (0, B(s, \rho))$ is given by the smallest non-negative integer r satisfying the inequality $r \geq r_\epsilon^*(G)$; that is, his *distribution-dependent* approximation $r_\epsilon^{(K)}(G)$ is given by

$$r_\epsilon^{(K)}(G) = \lceil r_\epsilon^*(G) \rceil, \quad (13)$$

where

$$r_\epsilon^*(G) = \begin{cases} \frac{1}{\ln \xi} \ln \left[\frac{\epsilon(1 - \rho + \rho B(s, \rho))}{B(s, \rho)(1 - \rho + \rho \epsilon)} \right], & \rho < 1, \\ \frac{1}{2}(1 + c^2) \left(\frac{1}{\epsilon} - \frac{1}{B(s, 1)} \right), & \rho = 1. \end{cases}$$

See Choi *et al.* [23] for a two-moment approximation similar to Equation (13). From Equation (13), the quotient $r_\epsilon(G)/r_\epsilon(M)$ can be approximated by the quantity

$$\theta(G) = \frac{r_\epsilon^*(G)}{r_\epsilon^*(M)} = \begin{cases} \frac{\ln \rho}{\ln \xi}, & \rho < 1, \\ \frac{1}{2}(1 + c^2), & \rho = 1. \end{cases}$$

Note that $\theta(G)$ is independent either of the acceptance level ϵ or of the number of servers s if ρ is fixed to a constant. From this property and numerical observations, Kimura [47] also provided a simple *two-moment* approximation $r_\epsilon^{(K)}(c^2)$, which is

$$r_\epsilon^{(K)}(c^2) = r_\epsilon(M) + \text{NINT}\left(\frac{1}{2}(c^2 - 1)\sqrt{\rho}r_\epsilon(M)\right), \quad (14)$$

where $\text{NINT}(x)$ is the function that returns the nearest integer of x . Another two-moment approximation for r_ϵ was developed by Tijms [36, Equation (4.8.20)], which is

$$r_\epsilon^{(T)}(c^2) = c^2 r_\epsilon(M) + (1 - c^2)r_\epsilon(D), \quad (15)$$

where $r_\epsilon(D)$ is the optimal buffer size for the associated $M/D/s/s+r$ queue. Clearly, $r_\epsilon^{(T)}(c^2)$ is based on the idea of system

interpolations shown in Equation (7). From numerical tests, we see that all of these approximations work well, independently on the number of servers s , even for small capacity cases; see Choi *et al.* [23] and Smith [51] for further numerical experiments of the two-moment approximations. Also, we see that the distribution-dependent approximation becomes more accurate than the two-moment approximations when service times are highly variable and a severe acceptance level is required in that system.

THE $M/G/s/s$ QUEUE

JEFFREY P. KHAROUFEH

Department of Industrial Engineering,
University of Pittsburgh, Pittsburgh,
Pennsylvania

INTRODUCTION

The $M/G/s/s$ queueing system is perhaps the most important and popular model for analyzing service systems characterized by random arrival patterns, random processing times, and a limited number of resources. It has been especially useful for telephone network design, the performance evaluation of telecommunications systems, and the design and analysis of large-scale service systems (e.g., customer contact centers). Most of the main results for the model were developed within the first three decades of the twentieth century, and the model's utility and importance have grown since that time.

In the parlance of Kendall's notation [1], the abbreviation $M/G/s/s$ means that the customer arrival process is Markovian or memoryless (M), the service times follow a general distribution (G), there are s identical servers ($s \geq 1$), and the total system capacity is limited to s (i.e., there is no waiting space in the system). The absence of a waiting space implies that customers who arrive to find all s servers busy leave and do not retry their service later. These customers are said to be lost. The $M/G/s/s$ queue is often called the *Erlang loss system*, since its development can be traced primarily to the Danish mathematician, Agner Krarup Erlang (1878–1929).

The popularity of the $M/G/s/s$ model stems from the simplicity of the steady-state probability distribution of the number of busy servers, which makes it easy to estimate the proportion of customers that are lost by the system in the long run. This performance parameter is an important measure of service quality in many practical contexts. For example, the lost customers might

represent vehicles arriving to a parking garage to find no vacant parking spaces. The garage owner forfeits a fraction of the revenue that he or she would have obtained if another parking space were available. In telecommunications applications, the lost customers may represent lost data packets that contain critical information. For either case, the service provider is concerned with minimizing the proportion of lost customers to ensure a high quality of service. The steady-state distribution of the number of busy servers also provides an estimate of the utilization of the system's resources in the long run.

The next section provides a mathematical description of the $M/G/s/s$ system and presents the main results for its steady-state behavior, namely, the steady-state distribution of the number of occupied servers and the steady-state blocking probability.

MODEL DESCRIPTION AND THE ERLANG B FORMULA

In an $M/G/s/s$ queue, customers arrive to the system according to a homogeneous Poisson process with rate parameter λ ($\lambda > 0$), and the service times form an independent and identically distributed (i.i.d.) sequence of nonnegative random variables with finite mean τ . The *offered load* to the system is the dimensionless quantity

$$a \equiv \lambda\tau.$$

The offered load per server, often termed the *traffic intensity*, is given by

$$\rho \equiv \frac{\lambda\tau}{s} = \frac{a}{s}.$$

Denote by $Q(t)$ the number of occupied servers (or equivalently, the number of customers in the system) at time t . Note that $\{Q(t) : t \geq 0\}$ is a stochastic process on the state space $S = \{0, 1, 2, \dots, s\}$. Let Q denote

the steady-state number of busy servers and define the probability mass function (p.m.f.) of Q by

$$p_j = \lim_{t \rightarrow \infty} P(Q(t) = j) = P(Q = j), \\ j = 0, 1, 2, \dots, s.$$

Owing to the fact that, at most, a finite number of customers can be present in the system, the existence of the steady-state distribution p_j , $0 \leq j \leq s$, is ensured. Using a reversibility argument, as outlined by Gross and Harris [2] and detailed in Ref. 3, it can be shown that

$$p_j = \frac{a^j/j!}{\sum_{i=0}^s a^i/i!}, \quad j = 0, 1, 2, \dots, s. \quad (1)$$

Equation (1) indicates that Q has a truncated Poisson distribution with parameter a , the offered load. The attractive feature of the steady-state distribution is that it depends on the service time distribution only through its mean (since $a = \lambda\tau$) and is otherwise insensitive to the form of the distribution. This *insensitivity property* is extremely useful for real applications when service times may be distinctly nonexponential. Because Poisson arrivals see time averages [PASTA, [4,5]], the long-run proportion of arriving customers who see s servers busy (and are blocked from receiving service) is precisely p_s . The formula for this blocking probability, termed the *Erlang B formula*, is

$$B(s, a) \equiv p_s = \frac{a^s/s!}{\sum_{j=0}^s a^j/j!}. \quad (2)$$

The Erlang B formula is a fundamental result for telephone traffic engineering problems and can be used to select the appropriate number of trunks (servers) needed to ensure a small proportion of lost calls (customers).

Several important properties of the function $B(s, a)$ can easily be derived. For example, for a fixed, the blocking probability $B(s, a)$ monotonically decreases to zero as s increases, and for s fixed, $B(s, a)$ monotonically increases to unity as a increases. Other

properties, such as convexity of the loss formula, have been discussed in Refs 6–8, among others. The Erlang B formula can also provide valuable insights into the behavior of large systems. For instance, Equation (2) can be used to show that it is more efficient to use a single large system with pooled servers than to use multiple smaller systems.

The next section examines the case when service times follow an exponential distribution. We discuss loss systems as well as systems with additional waiting spaces.

EXPONENTIAL SERVICE AND THE ERLANG C FORMULA

If the service times are independent and identically distributed exponential random variables with mean $1/\mu$, the system is an $M/M/s/s$ queue and $Q(t) : t \geq 0$ is a Markov process, namely, a birth-and-death process with birth rates

$$\lambda_j = \begin{cases} \lambda, & \text{if } j = 0, 1, 2, \dots, s-1, \\ 0, & \text{if } j = s, \end{cases}$$

and death rates

$$\mu_j = \begin{cases} j\mu, & \text{if } j = 1, 2, \dots, s, \\ 0, & \text{if } j = 0. \end{cases}$$

In this case, $\lambda\tau = \lambda/\mu$, so the Erlang B formula is [2]

$$B(s, a) = \frac{(\lambda/\mu)^s/s!}{\sum_{j=0}^s (\lambda/\mu)^j/j!}. \quad (3)$$

Related to the Erlang B formula is the *Erlang C formula* (or *Erlang delay formula*) for the $M/M/s$ system (or *Erlang delay system*), which includes an infinite-capacity queue to accommodate arriving customers who find all s servers busy. For this model, p_s is interpreted as the long-run proportion of customers who experience a delay before their service begins. The model assumes that the customers are willing to wait as long as they wish to receive service. The Erlang C

formula is given as [9]

$$C(s, a) = \frac{\frac{a^s}{s!(1-\rho)}}{\sum_{i=0}^{s-1} \frac{a^i}{i!} + \frac{a^s}{s!(1-\rho)}}, \quad 0 < a < s, \quad (4)$$

where $\rho = \lambda/s\mu$. Note that Equation (4) does not hold for arbitrary service time distributions, and it requires that the traffic intensity (ρ) is strictly less than unity.

As one might expect, a simple relationship exists between the Erlang B formula of Equation (2) and the Erlang C formula of Equation (4). It can be shown that [9]

$$C(s, a) = \frac{sB(s, a)}{s - a[1 - B(s, a)]}, \quad 0 < a < s.$$

COMPUTATIONAL ISSUES

When a and s are large, it can be difficult to compute the right-hand side of Equation (2) due to the presence of factorials and potentially very large powers. However, the blocking probability can be much more easily computed by using a recursive scheme. As before, let

$$B(s, a) \equiv \frac{a^s/s!}{\sum_{i=0}^s a^i/i!}$$

denote the blocking probability when an s -server system is offered a units of Poisson traffic. By analyzing the reciprocal of $B(s, a)$, it is not difficult to derive the recursion

$$B(k, a) = \frac{aB(k-1, a)}{k + aB(k-1, a)}, \quad k = 1, 2, \dots, s, \quad (5)$$

where $B(0, a) \equiv 1$. This recursion can be easily implemented in a spreadsheet or a computer program to obtain the blocking probability for systems with very large numbers of servers that are heavily loaded. To illustrate, consider a system with $s = 10^4$ servers that is offered $a = 10^4$ units of Poisson traffic. Computing $B(s, a)$ by Equation (5), the steady-state blocking probability is

$$B(10^4, 10^4) \approx 0.00794.$$

This means that about 0.8% of customers will be blocked from service.

When designing a new system, an important consideration is whether to use multiple small systems or to pool servers in one larger system. Suppose that the first option is to operate two different loss systems, one with s_1 servers handling a_1 units of traffic and the second with s_2 servers handling a_2 units of traffic. The alternative is to operate a single larger system with $s = s_1 + s_2$ servers and a combined offered load of $a = a_1 + a_2$. Is it more efficient to operate the single larger system or the two smaller systems? This question can be answered using the Erlang B formula. Suppose that $s_1 = 100$, $s_2 = 50$, $a_1 = 100$, and $a_2 = 100$. The proportion of blocked customers in the first system is

$$B(s_1, a_1) \approx 0.0757.$$

The proportion of blocked customers in the second system is

$$B(s_2, a_2) \approx 0.5093.$$

Therefore, the combined total proportion of lost customers between the two small systems is approximately 59%. If, on the other hand, all of the servers are pooled in a single system with $s = s_1 + s_2 = 150$ servers, and the two traffic streams are combined so that the offered load is $a = a_1 + a_2 = 200$, then the blocking probability is

$$B(s, a) = B(150, 200) \approx 0.26318.$$

That is, the larger service system reduces the (overall) proportion of lost customers by more than 50%. In general, it can be shown that $B(s_1 + s_2, a_1 + a_2) < B(s_1, a_1) + B(s_2, a_2)$.

FURTHER READING

Classical textbooks that provide further details on the standard $M/G/s/s$ model include Refs 2, 3, 5, and 9.

Important properties of the loss and delay formulae have been studied by many researchers. Jagerman [8] provided convexity results for the Erlang loss function. Harel and

Zipkin [10] proved strong convexity results for the average sojourn time in an $M/M/c$ system. Harel [7] showed that the proportion of lost customers in an $M/G/s/s$ system is convex in the arrival rate, provided that the traffic intensity is below a threshold. Jagers and van Doorn [11] proved the convexity of functions that generalize the Erlang loss and delay functions. Some simple inequalities for the performance parameters of multi-server queues, including loss systems, were provided by Sobel [12]. Harel [6] provided sharp bounds and simple approximations for the loss and delay formulae. Recently, Adelman [13] contributed simple algebraic approximations to the blocking formula using Palm calculus [14], which equates long-run event averages to long-run time averages. Ross and Seshadri [15] provided methods for estimating the expected time until the first customer is lost by the system.

Other authors have extended the basic model to include more complex and realistic dynamics. For instance, Brumelle [16] considered state-dependent systems with arrival and service rates that depend on the number of busy servers. The transient analysis of the Erlang loss system was considered by Abate and Whitt [17] and Grier *et al.* [18]. Systems with time-varying arrival and/or service rates have been studied by Davis *et al.* [19], and more recently by Knessl and Yang [20]. Lin and Ross [21] considered optimal admission control policies for a single-server Erlang loss model. Ziya *et al.* [22] analyzed the optimal pricing of customers in a loss model.

THE $M/M/1$ QUEUE

MYRON HLYNKA
Department of Mathematics
and Statistics, University of
Windsor, Ontario, Canada

In a queueing system, customers arrive for service, may wait for some time in a queue before entering service, receive service, and then leave. But these “customers” need not be people. Customers could be computer commands, telephone messages, items on a store shelf, or cars in a parking lot. Two classic books on queueing theory are by Gross *et al.* [1] and Kleinrock [2]. Other books on queueing include Bolch *et al.* [3] and Medhi [4]. For a web site with extensive queueing references, see Hlynka [5].

The $M/M/1$ queue uses Kendall’s notation. The first M (which stands for Markov or memoryless) means that the interarrival times are independent exponentially distributed random variables with arrival rate λ customers per unit time. Equivalently, we often say that arrivals follow a Poisson process with rate λ . The second M means that the service times are independent exponentially distributed random variables with service rate μ . The number 1 in Kendall’s notation indicates that there is a single server. Other assumptions that are usually made with this model are as follows:

- (a) there is an infinite buffer (waiting area) to hold customers;
- (b) customers are served in a first-in, first-out (FIFO) manner.

We can illustrate a single server first-in first-out queue as

** ... ** Server

where each * represents a customer. Figure 1 shows the number of customers in a typical $M/M/1$ queueing system versus time.

Two books with extensive discussion of $M/M/1$ queues are Robert [6] and Asmussen [7].

WHY IS THE $M/M/1$ MODEL SO POPULAR?

There are several reasons for the popularity of the $M/M/1$ queueing model. First, the $M/M/1$ queue is the easiest queue to analyze (other than the $D/D/1$ queue). The memoryless property means that if we know the current state of the system, we do not have to keep track of the past in order to find probabilities of future events. This keeps the mathematics and notation easier than it would be in more complex models.

Second, the assumptions of the $M/M/1$ queueing model are reasonable for several common models in the real world. Interarrival times are exponentially distributed with rate λ if customers behave independently of each other in making a decision whether to seek service at a particular time. Thus, arrivals to a barber shop or telephone calls to a call center can be expected to follow a Poisson process.

Models for which service times are exponentially distributed not as common as models for which interarrival times are exponentially distributed. However, exponentially distributed service times make sense in situations where most customers have a short service time but some customers need longer time lengths. An example of exponentially distributed service times might be the times required to process vehicles crossing the Canada/US border. Most customers with a passport and nothing to declare can be processed quite quickly. Others, with passports from countries other than Canada or the United States, or with large purchases, will take a much longer time. Similarly, transactions with a bank teller might be modeled by an exponential distribution.

A third reason that $M/M/1$ queueing systems are popular in the queueing literature is that they form an excellent base case, which can be used as a comparison for generalizations of such models. So $M/G/1$ models, $GI/M/1$ models, $M/M/s$ models, or $M/E/1$ models are all generalizations of $M/M/1$ models.

Figure 1. Number of customers versus time.

BIRTH-AND-DEATH TYPE FORMULATION

A standard $M/M/1$ queueing system is a special case of a birth-and-death process. Arrivals to the queue are considered to be births and service completions are considered to be deaths. The state of the system is taken to be the number of customers in the system (Fig. 2).

Given that there are i customers in an $M/M/1$ queueing system at a fixed point in time, let $p_{ij}(t)$ be the probability of having j customers in the system t time units later. We say that a function f is $o(t)$ if $\lim_{t \rightarrow 0} \frac{f(t)}{t} = 0$. In a small time Δt , the assumptions of a Poisson process require that the probability of two or more changes (arrivals or service completions) is $o(\Delta t)$ (“little oh”). It is also assumed that the probability of an arrival in a small time interval is approximately proportional to the length of the interval and the probability of a service completion in a small time interval is approximately proportional to the length of the interval. Thus, we have the following for $j = 1, 2, \dots$

$$p_{ij}(t + \Delta t) = p_{i,j-1}(t)\lambda\Delta t + p_{i,j+1}(t)\mu\Delta t + p_{ij}(t)(1 - \lambda\Delta t - \mu\Delta t) + o(\Delta t).$$

Subtract $p_{ij}(t)$ and divide by Δt to get

$$\frac{p_{ij}(t + \Delta t) - p_{ij}(t)}{\Delta t} = \lambda p_{i,j-1}(t) + \mu p_{i,j+1}(t) - (\lambda + \mu)p_{ij}(t) + \frac{o(\Delta t)}{\Delta t}.$$

Let $\Delta t \rightarrow 0$ and recall that $f'(t) = \lim_{\Delta t \rightarrow 0} \frac{f(t + \Delta t) - f(t)}{\Delta t}$. Thus

$$p'_{ij}(t) = p_{i,j-1}(t)\lambda + p_{i,j+1}(t)\mu - p_{ij}(t)(\lambda + \mu) \text{ for } j = 1, 2, \dots$$

When $j = 0$, we can obtain a simpler expression

$$p'_{i0}(t) = p_{i,1}(t)\mu - p_{i0}(t)\lambda.$$

These differential equations are called the *Chapman–Kolmogorov* equations and are the stepping stones to many other results about the $M/M/1$ queue.

LIMITING PROBABILITIES FOR THE M/M/1 QUEUE

We are interested in limiting probabilities $\lim_{t \rightarrow \infty} p_{ij}(t)$, which give the probability of having j customers in the system far in the future, if we begin with i customers initially. Such limiting probabilities may not exist for

Figure 2. Transition diagram for an $M/M/1$ queue.

Figure 3. Transient probabilities tending to the same limit.

some queueing systems. For example, if we begin with 0 customers and exactly one customer arrives at the end of each minute and requires exactly 50 s of service then the number of customers would alternate between 0 and 1 with changes at regular intervals of time, so there would be no limit. However, this regular periodicity does not happen for an $M/M/1$ queueing system. If $\lambda > \mu$, then the number of customers in the queueing system will tend to grow larger and larger so the limiting probability of being in a particular state j would be 0 for all $j = 0, 1, \dots$. However, it can be shown that limiting probabilities for an $M/M/1$ queueing system exist and are nonzero iff the arrival rate λ is less than the service rate μ (i.e., $\lambda < \mu$).

Given that the limiting probabilities exist, it is reasonable to expect that the initial number of customers will lose importance after a long period of time and that the graph of $p_{ij}(t)$ will approach some limiting value. Thus $\lim_{t \rightarrow \infty} p'_{ij}(t) = 0$, and we can define $\pi_j = \lim_{t \rightarrow \infty} p_{ij}(t)$ which does not depend on the initial value i . In Fig. 3, we show a plot of $p_{i2}(t)$ for $\lambda = 4$, $\mu = 5$, and $i = 0, 1, 2, 3, 4$, which shows all of the probability

curves tending toward the same limiting value π_2 .

Thus far we do not know the values of $p_{ij}(t)$ and π_j . It turns out that the former are very complex and difficult to obtain, while the latter are very simple and easy to obtain. If we take the Chapman–Kolmogorov equations and let $t \rightarrow \infty$, we obtain

$$0 = \pi_{j-1}\lambda + \pi_{j+1}\mu - \pi_j(\lambda + \mu) \text{ for } j = 1, 2, \dots \quad (1)$$

$$0 = \pi_1\mu - \pi_0\lambda. \quad (2)$$

These two equations are important and can be obtained in a more intuitive manner by considering a balance equation “rate in equals rate out” approach. If $j > 0$, then state j can be entered only from states $j - 1$ or state $j + 1$. Thus the rate into state j is $\pi_{j-1}\lambda + \pi_{j+1}\mu$. The system leaves state j if there is an arrival or service completion, so the rate out of state j is $\pi_j(\lambda + \mu)$. Equating these two rates gives Equation (1). Equation (2) follows in a similar manner.

In general, we define $\rho = \frac{\lambda}{s\mu}$ where s is the number of servers. For the $M/M/1$ queue, we have $s = 1$ and in this case, ρ may be referred

to as the *traffic intensity* or the *utilization factor*.

Theorem 1. *The limiting probabilities π_j of having j customers in an M/M/1 queueing system exist if $\lambda < \mu$. In this case,*

$$\pi_j = \rho^j(1 - \rho) \text{ for } j = 0, 1, \dots$$

Proof. We can solve Equations 1 and 2 recursively to obtain

$$\begin{aligned}\pi_1 &= \frac{\lambda}{\mu}\pi_0 = \rho\pi_0, \\ \pi_2 &= \frac{\lambda}{\mu}\pi_1 = \rho\pi_1 = \rho^2\pi_0.\end{aligned}$$

In general,

$$\pi_j = \rho^j\pi_0 \text{ for } j = 0, 1, \dots$$

If we sum both sides over all j , the left hand side becomes 1 and the right hand side becomes $\frac{\pi_0}{1-\rho}$ provided $0 < \rho < 1$. Thus, we find $\pi_0 = 1 - \rho$ and the result follows.

A corollary to this result is that the probability of having at least k customers in the system is ρ^k . The limiting probabilities are also called *steady-state* probabilities and *stationary* probabilities in this setting. The probability π_i represents the probability that the system is in state i (i.e., has i customers) at any point in time far in the future and also represents that long run proportion of time that the system has i customers. We observe in the above theorem, that the limiting probabilities depend on λ and μ only through ρ .

The Camcorder Principle

Suppose we make a video recording of a queueing system with arrivals and service completions. We could replay our video either in slow motion or in high speed. Certain properties of the system would not depend on the speed of playback while other properties would change. For example, the proportion of time that the queueing system is empty

would not depend on the speed. Similarly the probability (or proportion of time) that there are i customers in the system and the expected number of customers would not depend on the speed. However, if we double the speed, the time to serve a customer W_s and the time a customer must wait in the system W would be halved.

We know that the expected number of customers in an M/M/1 queueing system depends on λ and μ as these are the only parameters of the system, but based on our heuristic argument, multiplying the speed by any c would not affect the expected number of customers in the system. Let L be the expected number of customers in the system. Then the expected number of customer is, for some function g ,

$$E(L) = g(\lambda, \mu) = g(c\lambda, c\mu) \text{ for all } c > 0.$$

Choose $c = 1/\mu$ to get $E(L) = g(c\lambda, c\mu) = g(\lambda/\mu, 1) = g(\rho, 1)$. Thus, we see that $E(L)$ is a function of ρ alone. The same argument can be made for several other characteristics of queueing systems.

Theorem 2. *For an M/M/1 queueing system with arrival rate λ , service rate μ , and $\rho = \lambda/\mu$, the expected number of customers in the system is*

$$E(L) = \frac{\rho}{1 - \rho}.$$

Proof.

$$E(L) = \sum_{i=0}^{\infty} i\pi_i = \sum_{i=0}^{\infty} i\rho^i(1 - \rho) = \frac{\rho}{1 - \rho}.$$

PASTA Principle

PASTA is an acronym for Poisson Arrivals See Time Averages [8,9]. Since an M/M/1 system has arrivals entering the system according to a Poisson process, the PASTA principle does apply. For an example of where PASTA does not apply, suppose we had a queueing system with arrivals exactly 1 min apart and service times of 50 s (i.e.,

arrivals do not form a Poisson process). If we begin with one customer in the system, then there will be 50 s periods with exactly one customer in the system and 10 s periods with exactly zero customers in the system. Thus the average number of customers (over time) is 5/6. However, every arriving customer will see a system with zero customers. In contrast, if arrivals enter the system according to a Poisson process, the expected number of customers in the system at the time of arrival will be $E(L)$, the length of the system averaged over time.

Theorem 3. *For an M/M/1 queueing system with arrival rate λ , service rate μ , and $\rho = \lambda/\mu$, the expected wait for a randomly arriving customer is*

$$E(W) = \frac{1}{\mu - \lambda}.$$

Proof. According to the PASTA principle, a randomly arriving customer will see i customers in the system with probability π_i . If there are i customers in the system when a new customer arrives, the expected time to complete service for the new customer will be the sum of the service times for the i customers in the system plus the service time for the new customer. Each customer has mean service time $1/\mu$ because service times are exponentially distributed (and hence memoryless). This even applies to the customer in service (if any). Thus the expected service time for a randomly arriving customer, given that there are i customers currently in service, is $\frac{i+1}{\mu}$. Hence

$$\begin{aligned} E(W) &= \sum_{i=0}^{\infty} \pi_i \frac{i+1}{\mu} = \frac{1}{\mu} \sum_{i=0}^{\infty} i\pi_i + \frac{1}{\mu} \sum_{i=0}^{\infty} \pi_i \\ &= \frac{E(L) + 1}{\mu} = \frac{1}{\mu - \lambda}. \end{aligned}$$

We now introduce (and repeat) some common notation:

- L the number of customers in the queueing system (includes customers waiting or in service)

- L_q the number of customers in the queue (this excludes the customer in service, if any)
- L_s the number of customers in service (this will be 0 or 1)
- W system time (includes waiting and service) for a randomly arriving customer
- W_q waiting time in the queue (excludes service time) for a randomly arriving customer
- W_s service time of a randomly arriving customers (excludes any waiting time)

The following is the most famous result in queueing theory, first proved by Little [10].

Theorem 4. [Little's Theorem (Little's Law)]. *For an M/M/1 queueing system*

$$E(L) = \lambda E(W).$$

This theorem is far more general than the special case given above. It also applies to the more general GI/G/s queues and adds the two additional results

$$\begin{aligned} E(L_q) &= \lambda E(W_q), \\ E(L_s) &= \lambda E(W_s). \end{aligned}$$

We have the following important results for an M/M/1 system:

$$\begin{aligned} E(L) &= \frac{\rho}{1 - \rho}, \\ E(L_q) &= \frac{\rho^2}{1 - \rho}, \\ E(L_s) &= \rho, \\ E(W) &= \frac{1}{\mu - \lambda}, \\ E(W_q) &= \frac{\lambda^2}{\mu(\mu - \lambda)}, \\ E(W_s) &= \frac{1}{\mu}. \end{aligned}$$

A result that relates $E(W)$ to $E(L)$ for the M/M/1 queueing system (only) using μ instead of λ is $E(W) = \frac{E(L)+1}{\mu}$.

For an M/M/1 queueing system, the system will alternate between being empty

and having at least one customer in service. The length of time between empty systems is called a *busy period*. Since there can be various numbers of customers during such times, one can reasonably expect that the busy period distribution would be quite complex. However, we can get information about the busy period in a number of clever ways.

Alternating Renewal Process Approach

An $M/M/1$ queueing system alternates between being empty and nonempty. A renewal occurs when a system becomes empty. Since interarrivals are exponentially distributed with rate λ , the system stays empty for an exponentially distributed time with expected value $1/\lambda$. Then the server stays busy for time B with expected value $E(B)$. But we know that the long run proportion of time that the system is empty is $\pi_0 = 1 - \rho$, so $1 - \rho = \frac{1/\lambda}{E(B) + 1/\lambda}$. Solving gives $E(B) = \frac{\lambda}{\mu(\mu - \lambda)}$.

Probabilistic Interpretation of Laplace Transform Approach

In queueing theory, many results are expressed in terms of Laplace Transforms. Recall that if X is a random variable with positive support and probability density function (pdf) $f(x)$, then the Laplace transform of $f(x)$ is given by

$$L_X(s) = \int_0^\infty f(x)e^{-sx} dx.$$

It can be shown that $L_X(s) = P(X < Y)$, where Y is exponentially distributed with rate s and independent of X . Here Y is sometimes called a *catastrophe*.

Theorem 5. *If B is the busy period of an $M/M/1$ queueing system, then*

$$L_B(s) = \frac{(\lambda + \mu + s) - \sqrt{(\lambda + \mu + s)^2 - 4\lambda\mu}}{\lambda}.$$

Proof. $L_B(s) = P(B < Y)$ where Y is exponentially distributed at rate s and independent

of B . A busy period begins with the arrival of a single customer to an empty system. The next event is a service completion, an arrival or a catastrophe Y . If the next event is a service completion, then $B < Y$. If the next event is arrival, then we are in the original situation except that we have two customers in the system and we must complete two busy periods before the catastrophe. Thus

$$\begin{aligned} L_B(s) &= P(B < Y) \\ &= \frac{\mu}{\lambda + \mu + s} + \frac{\lambda}{\lambda + \mu + s} L_B(s)^2. \end{aligned}$$

This is a quadratic in $L_B(s)$ and we get two possible solutions.

$$L_B(s) = \frac{(\lambda + \mu + s) \pm \sqrt{(\lambda + \mu + s)^2 - 4\lambda\mu}}{\lambda}.$$

We have two possible solutions because of the $\pm$ in the numerator. However, since we now know that a Laplace Transform is actually a probability, we reject the “+” possibility as it would make the $L_B(0) = 2$.

Level Crossing Method

Another important consideration in the study of $M/M/1$ queues is the distribution of the waiting time W_q for a randomly arriving customer. One of the fastest ways of obtaining this result is to use Brill’s level crossing method [11]. In this method, the down crossing rate of any level equals the upcrossing rate. However, unlike the rate-in equals rate-out approach, the level crossing method remarkably gets enough information to determine the entire pdf. Define the server workload at time t to be the time that the server needs to complete service for all customers in the system at time t . This workload is a decreasing function (with slope -1) at every point except where an arrival occurs and the value jumps by the service time requirement of the arrival. See Fig. 4 for a typical workload graph.

By the PASTA principle, W_q has the same pdf $f(w)$ as the workload. For a fixed w , the down-crossing rate (for $w > 0$) is $f(w)$. The upcrossing rate can be partitioned into

Figure 4. Workload for an $M/M/1$ queue.Figure 5. Expected $M/M/1$ queue length at time t .

two cases—either the randomly arriving customer encounters an empty system (with probability $\pi_0 = 1 - \rho$) and the jump in workload is greater than w or the system is at level $y > 0$ and the jump in workload is greater than $w - y$. The jump size from 0 is greater than w or $w - y$ with probability $e^{-\mu w}$ or $e^{-\mu(w-y)}$ respectively. This gives rise to the integral equation

$$f(w) = (1 - \rho)\lambda e^{-\mu w} + \int_0^x \lambda f(y) e^{-(w-y)\mu} dy,$$

where $(1 - \rho) + \int_0^\infty f(w) dw = 1$. It is easy to see check that

$$f(w) = \rho(\mu - \lambda)e^{-(\mu-\lambda)w} \text{ for } w > 0,$$

with $P(W_q = 0) = 1 - \rho$, is the solution.

A related result states that the pdf of the system time of a random arriving customer to an $M/M/1$ queueing system is $g(w) = (\mu - \lambda)e^{-(\mu-\lambda)w}$ for $w > 0$.

TRANSIENT RESULTS

Steady state ($t \rightarrow \infty$) results for an $M/M/1$ queueing system are much easier to derive and much simpler to express than transient results (for finite t). Jain *et al.* [12] devote considerable attention to transient queueing results. One key result in transient analysis is given by the following theorem.

Theorem 6. Assume that there are i customers at time 0 in an M/M/1 queueing system, with arrival rate λ and service rate μ . Let $p_{in}(t)$ be the probability of having n customers at time t . Then

$$p_{in}(t) = e^{-(\lambda+\mu)t} [\rho^{(n-i)/2} I_{n-i}(2\sqrt{\lambda\mu t}) + \rho^{(n-i-1)/2} I_{n+i+1}(2\sqrt{\lambda\mu t})] + e^{-(\lambda+\mu)t} (1-\rho) \rho^n \sum_{j=n+i+2}^{\infty} I_j(2\sqrt{\lambda\mu t}) / \rho^{j/2},$$

where $I_n(t)$ is the modified Bessel function of the first kind.

Since we have an expression for the transient probabilities $p_{in}(t)$, we can find other performance measures such as the expected number of customers $E(L_i(t))$ in the system at time t if the system has i customers at time 0. Figure 5 shows $E(L_i(t))$ versus t for $\lambda = 4$, $\mu = 5$, and $i = 0, 1, \dots, 7$. All curves tend to $E(L) = \frac{\rho}{1-\rho}$ as $t \rightarrow \infty$.

THE $M/M/\infty$ QUEUE

BERNARDO D'AURIA
Departamento de Estadística,
Universidad Carlos III de
Madrid, Madrid, Spain

INTRODUCTION

The $M/M/\infty$ queue is one of the simplest queueing models and as such, is often used as a first approximation for any queueing system with no waiting line. Examples of these kind of systems may be encountered in physics; for example, radioactive emissions [1,2], highway traffic [3], telecommunication systems [4], emergency appliances' management in hospitals [5], and computer systems [6], to list just a few.

Following Kendall's notation, the abbreviation $M/M/\infty$ means that the arrival process is Markovian or memoryless (M), the service times follow an exponential distribution (the only continuous memoryless distribution (M)), and ∞ signifies that the system has an infinite set of servers to satisfy customers' requests. The system has no waiting room, thus a new customer begins to be served immediately and leaves the system as soon as his/her exponential service request is satisfied. The first contribution to the analysis of the stationary behavior of the $M/M/\infty$ queue was due to Erlang [7].

The popularity of the $M/M/\infty$ queue can be attributed to a simple form of the steady-state distribution of the number of customers in the system, given by a Poisson random variable. The mean of this random variable, often referred to as the *traffic intensity*, is the ratio of the arrival and the service rates. This special form of the stationary distribution is shared by all $M/G/\infty$ systems, a property known as *insensitivity*. According to this property, the stationary distribution of the number of customers in the system depends on the

service distribution only through the service distribution mean and not its full form [8].

MODEL DESCRIPTION

We begin our considerations with the $M/M/\infty$ system starting empty at time 0. Let (τ_n, S_n) with $n > 0$ be a sequence of pairs such that for each n , τ_n is the n th interarrival time, the time interval between the arrivals of the $(n-1)$ th and the n th customers, and S_n is the service request of the n th customer.

We can easily see that $T_n = \sum_{i=1}^n \tau_i$ is the arrival time of the n th customer, $n > 0$, and taking into account that in the infinite server queue there is no waiting time, we can directly compute the departure time of the n th customer, D_n , as $D_n = T_n + S_n$.

The above definitions are valid for any infinite server queue, however in the special case of the $M/M/\infty$ queue, it is assumed that the sequences τ_n and S_n are independent of each other, both are iid exponential, the former with parameter $\lambda > 0$ and the latter with $\mu > 0$. Denoting by (τ, S) any generic pair of the underlying sequence, we see that the mean interarrival and service times are $\mathbb{E}[\tau] = 1/\lambda$ and $\mathbb{E}[S] = 1/\mu$, respectively, and hence the traffic intensity is $\rho = \lambda/\mu$.

Number of Customers in the System at Time t

The quantity of main interest in the queueing system is the number of customers present at time t denoted by $Q(t)$. This quantity can be expressed in terms of T_n and S_n as

$$Q(t) = \sum_{n=1}^{\infty} 1\{T_n \leq t < T_n + S_n\},$$

where $1\{\cdot\}$ is the indicator function of the set $\{\cdot\}$. The contribution of the n th customer to the sum takes place only if s/he is present in the queue at time t , which means that t falls in the interval $[T_n, D_n) = [T_n, T_n + S_n)$.

Figure 1. Transition diagram.

Keeping in mind that all variables considered are exponential, it can be easily seen that $Q(t)$ is a continuous-time Markov chain, which in particular can be viewed as a birth–death process with birth and death rates λ_n and μ_n given by

$$\begin{cases} \lambda_n = \lambda \\ \mu_n = n\mu, \end{cases} \quad n \geq 0. \quad (1)$$

In Fig. 1 the corresponding transition diagram is sketched.

If we define $p_n(t) = \Pr\{Q(t) = n\}$, it is possible to deduce the transient behavior of the system by an infinite system of differential equations given below, which are valid for the birth–death process:

$$\begin{cases} p'_0(t) = -\lambda p_0(t) + \mu p_1(t), & n = 0, \\ p'_n(t) = -(\lambda + n\mu)p_n(t) + \lambda p_{n-1}(t) \\ \quad + (n+1)\mu p_{n+1}(t), & n \geq 1, \end{cases} \quad (2)$$

which solved for $p_0(0) = 1$ leads to

$$p_n(t) = \frac{v(t)^n}{n!} e^{-v(t)}, \quad (3)$$

with $v(t) = \lambda \int_0^t e^{-\mu(t-x)} dx$. Therefore, the transient distribution of $Q(t)$ is a Poisson distribution with parameter $v(t)$

$$Q(t) \sim \text{Po}(\rho(1 - e^{-t\mu})). \quad (4)$$

STATIONARY BEHAVIOR

By allowing $t \rightarrow \infty$ in Equation (4), we get $v(t) \rightarrow \lambda/\mu = \rho$ and

$$Q(\infty) \sim \text{Po}(\lambda/\mu), \quad (5)$$

which can be interpreted as follows: under the stationary regime in the $M/M/\infty$ system with traffic intensity ρ , the number of customers in the system follows a Poisson distribution with mean ρ .

Another way of arriving at this result is to solve the stationary version of the infinite system (Eq. 2). After canceling the derivatives with respect to time, we obtain

$$\begin{cases} 0 = -\lambda p_0 + \mu p_1, & n = 0, \\ 0 = -(\lambda + n\mu)p_n + \lambda p_{n-1} \\ \quad + (n+1)\mu p_{n+1}, & n \geq 1, \end{cases} \quad (6)$$

with the ratio

$$\frac{p_n}{p_{n-1}} = \frac{\rho}{n},$$

which taking into account the normalizing condition $\sum_n p_n = 1$ yields

$$p_n = \frac{\rho^n}{n!} e^{-\rho}.$$

It is worth noticing that in this case the queue is always stable for any value of $\rho > 0$.

To construct a stationary version of the process, it is sufficient to consider an additional iid sequence of pairs (τ_n, S_n) now indexed over the negative integers $n < 0$, that corresponds to the sequence of the customers arriving before time 0. The arrival time of the n th customer, where $n < 0$, is given by $T_n = -\sum_{i=n}^{-1} \tau_i$. Subsequently, the augmented sequence $\{T_n\}_{n \neq 0}$ forms a stationary homogeneous Poisson point process on the real line.

Rate of Convergence to the Stationary Regime

Let $Q^*(t)$ be the stationary version of the process and $Q(t)$, as before, the system starting empty at time 0. Then, $Q^*(0) \geq Q(0) = 0$ a.s. and the coupling time $T^* = \inf_{t \geq 0} \{Q^*(t) = Q(t)\}$ is the moment of departure of the last of the customers present in the stationary system at time 0, with the number of those customers given by $Q^*(0)$. The tail of the

Figure 2. Busy and idle periods.

distribution of T^* can be calculated as

$$\begin{aligned}
 \Pr\{T^* > t\} &= \Pr\{\max\{S_1^*, \dots, S_{Q^*(0)}^*\} < t\} \\
 &= 1 - \mathbb{E}[\mathbb{E}[1\{\max\{S_1^*, \dots, S_{Q^*(0)}^*\} > t\} \\
 &\quad | Q^*(0)]] \\
 &= 1 - \mathbb{E}\left[(e^{-\mu t})^{Q^*(0)}\right] = 1 - \phi(e^{-\mu t}) \\
 &= 1 - e^{-\rho e^{-\mu t}},
 \end{aligned}$$

where $\phi(z) = e^{-\rho(1-z)}$ is the characteristic function of a Poisson distribution with parameter ρ , and $S_1^*, \dots, S_{Q^*(0)}^*$ are the residual service times of the customers present in the stationary system at time 0.

The upper bound on the convergence rate of the empty-started system to its stationary regime can be easily derived by employing the *coupling time inequality* (see Ref. 9)

$$d_v(Q(t), Q^*(t)) \leq \Pr\{T^* > t\} = 1 - e^{-\rho e^{-\mu t}}, \quad (7)$$

where by

$$d_v(X, Y) = \frac{1}{2} \sum_{k=0}^{\infty} |\Pr\{X = k\} - \Pr\{Y = k\}|;$$

we denote the total variation distance between the probability distributions of two arbitrary discrete random variables X and Y .

THE BUSY PERIOD DISTRIBUTION

In the M/M/∞ queue, a busy period is any time interval during which the system is continuously busy, that is with at least one customer in service. The busy period begins

when an empty system is entered by a new customer and ends as soon as the last served customer leaves the system empty again. The time interval between two consecutive busy periods is referred to as an idle period, during which the system remains empty.

The alternation of busy and idle periods can be viewed as an “On–Off” renewal process with the busy periods corresponding to the system being On and the idle to Off. In our considerations we assume that the system starts with an idle period of length I_0 followed by an interchange of iid pairs $\{(B_n, I_n)\}_n$, $n \geq 1$. In Fig. 2 a graphical representation of this renewal process is displayed, where V_t is the virtual remaining service time, that is the time the system would require to become empty if the arrival process were to be stopped at time t .

In this section we are concerned with the distribution of the generic pair (B, I) . Given the Poisson nature of the arrival stream, we immediately see that $I \sim \text{Exp}(\lambda)$. Moreover, since the sequence of the service requests is independent of that of the arrival times, we also notice that B and I are independent. In what follows, we derive the distribution of B using the original idea of Takács, see Ref. 11.

Let $N(t)$ be the process that counts the number of busy periods started before time t :

$$\{N(t) \geq n\} = \left\{ \sum_{k=0}^n C_k \leq t \right\},$$

where we set the cycle length $C_n = B_n + I_n$ with $B_0 = 0$. Notice that C_0 has a different distribution from the other C_n 's.

Let us introduce the (delayed) renewal function $m(t) = \mathbb{E}[N(t)]$, which satisfies the

following equation

$$m'(t) = \lambda p_0(t). \quad (8)$$

Hence, the rate of having a new busy period starting at time t is given by the joint occurrence of two events: the system being idle at time t^- and a new arrival at time t with rate λ . Now, $p_0(t)$, defined in Equation (3) and involved in the last equation can be written as $p_0(t) = \Pr\{Q(t) = 0\} = \Pr\{t \in \text{Idle period}\}$. Let $\pi(s) = \int_0^\infty e^{-st} p_0(t) dt$ be its Laplace transform.

We obtain the following

$$\begin{aligned} \Pr\{t \in \text{Busy period}\} &= 1 - p_0(t) \\ &= \int_0^t \Pr\{B > t - x\} dm(x), \end{aligned} \quad (9)$$

where we split the event $\{t \in \text{Busy period}\}$ into disjoint events, assuming that the busy period active at time t started at x , $x \in (0, t]$.

Let $\phi_B(s) = \mathbb{E}[e^{-sB}]$ be the Laplace–Stieltjes transform of B , and $\phi_I(s) = \lambda/(\lambda + s)$ that of I . Combining Equations (9) and (8) leads to

$$\phi_B(s) = \frac{1}{\phi_I(s)} - \frac{1}{\lambda \pi(s)} = \frac{B_1(s)}{B_0(s)}, \quad (10)$$

where

$$\begin{aligned} B_n(s) &= B_n(s; \lambda, \mu) \\ &= \int_0^1 (1-x)^n x^{s/\mu-1} e^{\lambda x/\mu} dx \\ &= \frac{\Gamma(n+1) \Gamma(s/\mu)}{\Gamma(n+1+s/\mu)} M\left(\frac{s}{\mu}, n+1+\frac{s}{\mu}, \frac{\lambda}{\mu}\right), \end{aligned} \quad (11)$$

where $M(a, b, z)$ is the hypergeometric ${}_1F_1$ generalized function; see formula (13.2.1) in Ref. 12.

The length of a busy period can also be seen as the first hitting time of level 0 by the process $Q(t)$, given that the process started at level 1, that is $B =_d T_1^*$ with $T_1^* = \inf_{t>0}\{Q(t) = 0 | Q(0) = 1\}$. This particular interpretation allows for the following generalization to be considered.

C-Congestion Periods and General Hitting Times

The C -congestion period, T_C^* , is defined as the first hitting time of level 0 for the process $Q(t)$, assuming that it started at level C . Compared with a more general notation of the hitting times,

$$T_a^*(b) = \inf_{t>0} \{Q(t) = b | Q(0) = a\},$$

we see that the argument b for the case of $b = 0$ has been suppressed. It follows that a busy period is nothing else than an 1-congestion period.

In Ref. 13 it was shown that

$$\phi_{T_C^*}(s) = \mathbb{E}[e^{-sT_C^*}] = \frac{B_C(s)}{B_0(s)},$$

whereas the Laplace transform of the hitting time $T_a^*(b)$ is

$$\phi_{T_a^*(b)}(s) = \begin{cases} B_a(s)/B_b(s), & 0 \leq a \leq b, \\ \Gamma_a(s)/\Gamma_b(s), & 0 \leq b \leq a, \end{cases} \quad (13)$$

with

$$\begin{aligned} \Gamma_n(s) &= \Gamma_n(s; \lambda, \mu) \\ &= \int_0^\infty (1 + \mu x/\lambda)^n x^{s/\mu-1} e^{-x} dx. \end{aligned} \quad (14)$$

For a proof of Equation (13) and additional information on historical references; see Proposition 6.7 in Ref. 10.

POISSON RANDOM MEASURES: A DIFFERENT PERSPECTIVE

An elegant and more powerful analysis of the model can be obtained by taking the single-sided or the double-sided sequences of pairs $\{(T_n, S_n)\}_n$ with $n > 0$ or $n \neq 0$ respectively, and regarding them as a collection of points in a two-dimensional space [14,15]. By doing so, we obtain a bidimensional random measure

$$N(A) = \sum_n \delta_{(T_n, S_n)}(A),$$

which is a Poisson Random Measure (PRM), such that for any borel set $A \subset \mathbb{R}^+ \times \mathbb{R}^+$

Figure 3. Poisson random measures perspective.

($A \subset \mathbb{R} \times \mathbb{R}^+$), it counts the number of points $\{(T_n, S_n)\}_n$ captured by A .

This result is a consequence of the fact that the sequence $\{T_n\}_n$ generates a Poisson point process and that the $\{S_n\}_n$ are independent. For more details see, for example, Proposition 3.8 in Ref. 16.

Figure 3 shows a measure-based representation of the number of customers in the $M/M/\infty$ system for the transient ($n > 0$) and the stationary ($n \neq 0$) scenarios.

From the PRM formulation, we get right away that for any borel set $A \subset \mathbb{R}^+ \times \mathbb{R}^+$ ($A \subset \mathbb{R} \times \mathbb{R}^+$)

$$N(A) \sim \text{Po}(|A|),$$

where $|A|$ is the measure of set A under the intensity measure $\nu(A)$ defined by

$$\nu(dt \times ds) = \lambda \mu e^{-\mu s} dt ds.$$

Additionally, any two disjoint sets A and B imply the independence of $N(A)$ and $N(B)$ written as

$$N(A) \perp N(B).$$

Putting everything together and referring to Fig. 4 we observe that

$$Q(t) = N(A_t) \quad \text{and} \quad Q(\infty) =_d Q^*(0) = N(A_0^*),$$

with

$$A_t = \{(x, y) | 0 \leq x \leq t, y > t - x\},$$

$$A_0^* = \{(x, y) | x \leq 0, y > |x|\}$$

and

$$|A_t| = \nu(A_t) = \nu(t),$$

$$|A_0^*| = \nu(A_0^*) = \rho$$

which leads to Equations (3) and (5).

Figure 4. Number of customers in the system.

Figure 5. Number of departures in the interval $[s, t]$.

The Departure Process

As shown in Fig. 5, the number of departures in the interval $[s, t)$ corresponds to the number of points falling into

$$A_{[s,t)} = \{(x, y) | 0 \leq x \leq t, (s - x)^+ \leq y < t - x\}$$

and

$$A_{[s,t)}^* = \{(x, y) | x \leq t, (s - x)^+ \leq y < t - x\},$$

with $(a)^+ = \max\{a, 0\}$.

As such, the output process of the $M/M/\infty$ system is a Poisson process, which in the transient case has rate

$$\begin{aligned} \lambda(t) &= \frac{d}{dt} v(A_{[0,t)}) = \frac{d}{dt} \int_0^t (1 - e^{-\mu(t-x)}) dx \\ &= \lambda(1 - e^{-\mu t}) \end{aligned}$$

and λ in the stationary case.

FURTHER READING

Further details on the classical $M/M/\infty$ queue can be found in standard textbooks such as Refs 17–23, to mention just a few. Nevertheless, the standard analysis of the $M/M/\infty$ queue encountered in books is often restricted to the proof of the stationary distribution of the number of customers given by Equation (5). A deeper analysis is generally reserved for the $M/G/\infty$ system that is a generalization of it. The exception is the textbook by Robert, Ref. 10, in which an entire chapter is dedicated to the Markovian system. An in-depth analysis of that chapter is based on the original martingale technique, that employs the earlier results of Ref. 24.

The treatment of the asymptotic properties of the $M/M/\infty$ system, can be found in, for example, Refs 25–28 and the references therein, while some interesting results on the analysis of the busy and congestion periods, in Refs 13, 29–34.

The transient analysis of the $M/M/\infty$ system and its $M/G/\infty$ extension have also been studied extensively, see for example Refs 5, 35, and 36 and the references therein.

Several authors provided numerous extensions of the underlying model to incorporate more complex and more realistic dynamics. In some cases, this has been achieved by introducing some level of dependence in the customers' behavior by allowing the service and the arrival rates to depend on the external random environment. Work in this direction can be found in Refs 37–41.

Department of Industrial Engineering,
University of Pittsburgh, Pittsburgh,
Pennsylvania

INTRODUCTION

The $M/M/s$ queueing system is one of the most fundamental models for designing, analyzing, and controlling stochastic service systems. Since the introduction of the model by Erlang nearly a century ago for telephone engineering applications, new applications have emerged, such as customer contact centers, hospitals, and web servers. Most of the main results for the model were developed within the first three decades of the twentieth century.

Using Kendall's notation [1], the nomenclature $M/M/s$ is described as follows: The arrival process is Markovian or memoryless (M); the service times are also memoryless (M); there are s identical servers ($1 \leq s < \infty$); and there is an infinite-capacity waiting room for customers who cannot be served upon arrival. Customers who arrive to find all s servers busy join the queue and wait as long as necessary for service, so that no customers are lost. Because there is a possibility that customers experience delay in the queue before they gain access to a server, the system is often called the *Erlang delay system*. Note that, if $s = 1$, the system is an $M/M/1$ queueing model (see **The $M/M/1$ Queue**), and when $s = \infty$, we have the $M/M/\infty$ system (see **The $M/M/\infty$ Queue**).

Although the $M/M/s$ model imposes some restrictive assumptions, such as exponential service times, it can still be utilized to design and analyze a variety of real service systems thanks, in part, to the simplicity of results describing its limiting behavior. For example, the model can be utilized to determine the optimal number of agents in a customer contact center (e.g., a call center)

to reduce the average waiting time in queue or the probability of being delayed when placing a call. In health-care service applications, the model can be used to determine the optimal number of beds, or the appropriate nurse staffing level, to achieve a minimum quality-of-service guarantee. The $M/M/s$ model can also be used to design a hospital ward that minimizes the proportion of patients who are forced to wait before being admitted. Besides these design considerations, the model provides an estimate of the utilization of the system's resources—an important indicator of efficiency.

The remainder of the article is organized as follows. The next section provides a mathematical description of the $M/M/s$ system and describes the steady-state (or limiting) behavior of the system. Subsequently, we discuss the $M/M/s/c$ system as a special case of $M/M/s$. The next two sections discuss the Erlang C formula, its structural properties, and computational issues. The final section provides suggestions for reading on the Erlang delay model.

MODEL DESCRIPTION AND PERFORMANCE PARAMETERS

The $M/M/s$ queue is a model for a stochastic service system to which customers arrive according to a homogeneous Poisson process with rate parameter λ ($\lambda > 0$), and the service requirement of each customer is distributed exponentially with mean $1/\mu$. The *offered load* to the system is the dimensionless quantity

$$a \equiv \frac{\lambda}{\mu}.$$

The offered load per server, often termed the *traffic intensity*, is given by

$$\rho \equiv \frac{\lambda}{s\mu} = \frac{a}{s}.$$

Owing to the Markovian nature of the arrival process and the service times, the state of

the system is completely characterized by the total number of customers in the system (i.e., the number of customers currently in service and those waiting in the queue to receive service). Denote by $Q(t)$ the number of customers in the system at time t , and note that $\{Q(t) : t \geq 0\}$ is a continuous-time Markov chain (CTMC) on the denumerable state space $S = \{0, 1, 2, \dots\}$. Under suitable conditions, as $t \rightarrow \infty$, the random variable $Q(t)$ converges in distribution to a random variable describing the steady-state number of customers in the system. Let Q denote this random variable and define the probability mass function (p.m.f.) of Q by

$$p_j = \lim_{t \rightarrow \infty} P(Q(t) = j) = P(Q = j), \\ j = 0, 1, 2, \dots$$

When the traffic intensity (ρ) is less than 1, the existence of the steady-state distribution, $\{p_j\}$, is ensured. The process, $\{Q(t) : t \geq 0\}$, is a birth-and-death process (see **Birth-and-Death Processes**) with birth rates $\lambda_j = \lambda$ for all j , and death rates

$$\mu_j = \begin{cases} j\mu, & \text{if } 0 \leq j < s, \\ s\mu, & \text{if } j \geq s. \end{cases}$$

The steady-state probabilities can be derived by solving the balance equations [2], and these equations, when solved simultaneously, yield

$$p_j = \begin{cases} \frac{(s\rho)^j}{j!} p_0, & \text{if } 0 \leq j < s, \\ \frac{\rho^j s^s}{s!} p_0, & \text{if } j \geq s, \end{cases} \quad (1)$$

where the normalization condition

$$\sum_{j=0}^{\infty} p_j = 1$$

shows that

$$p_0 = \left(\sum_{j=0}^{s-1} \frac{(s\rho)^j}{j!} + \frac{(s\rho)^s}{s!(1-\rho)} \right)^{-1}. \quad (2)$$

The mean performance parameters, namely, the steady-state mean number of

customers in the system (L), the steady-state mean number of customers in the waiting line (L_q), the steady-state mean time in the system (W), and the steady-state mean time in the waiting line (W_q), can be obtained by using Equations (1) and (2) and Little's Law [3]. The mean queue length can be directly obtained by using the steady-state probabilities

$$L_q = \sum_{j=s+1}^{\infty} (j-s)p_j = \frac{a^s \rho}{s!(1-\rho)^2} p_0. \quad (3)$$

By Little's Law, the mean time in the waiting line is $W_q = L_q/\lambda$,

$$W_q = \frac{a^s}{s!(s\mu)(1-\rho)^2} p_0. \quad (4)$$

The mean time in the system is $W = W_q + 1/\mu$,

$$W = \frac{1}{\mu} + \frac{a^s}{s!(s\mu)(1-\rho)^2} p_0. \quad (5)$$

Finally, the mean number of customers in the system is

$$L = a + \frac{a^s \rho}{s!(s\mu)(1-\rho)^2} p_0. \quad (6)$$

The cumulative distribution function (c.d.f.) of the steady-state delay, or waiting time in queue, is denoted by $F_q(t)$, and the total time in system has c.d.f. $F(t)$. By conditioning on the number of customers seen in the system by an arriving customer [3], and assuming $\rho < 1$, $F_q(t)$ and $F(t)$ are, respectively, given by

$$F_q(t) = 1 - \frac{a^s p_0}{s!(1-\rho)} e^{-(s\mu-\lambda)t}, \quad t \geq 0 \quad (7)$$

and

$$F(t) = \frac{s(1-\rho) - F_q(0)}{s(1-\rho) - 1} (1 - e^{-\mu t}) \\ - \frac{1 - F_q(0)}{s(1-\rho) - 1} (1 - e^{-(s\mu-\lambda)t}), \quad t \geq 0. \quad (8)$$

THE $M/M/s/c$ QUEUE

The $M/M/s/c$ queue is a special case of the $M/M/s$ system in which there is a limit (c) on the total number of customers in the system (i.e., the total number of customers in service and waiting in the queue is limited to c so that the capacity of the waiting area is $c - s$). An arriving customer who finds c customers in the system is lost and does not retry his/her service. The steady-state probabilities can be derived in a straightforward way (as in the $M/M/s$ case) except that the effective arrival rate of customers must account for the fact some proportion of arrivals will be turned away due to blocking. The steady-state probabilities for the $M/M/s/c$ system are given by

$$p_j = \begin{cases} \frac{(s\rho)^j}{j!} p_0, & \text{if } 0 \leq j < s, \\ \frac{\rho^j s^s}{s!} p_0, & \text{if } s \leq j \leq c. \end{cases} \quad (9)$$

To obtain p_0 , the same normalization procedure is utilized as in $M/M/s$ system; however, the series is finite, and, thus, we need not require that $\rho < 1$. Therefore,

$$p_0 = \begin{cases} \left(\sum_{j=0}^{c-1} \frac{a^j}{j!} + \frac{a^s}{s!} \frac{1 - \rho^{c-s+1}}{1 - \rho} \right)^{-1} & \text{if } \rho \neq 1, \\ \left(\sum_{j=0}^{c-1} \frac{a^j}{j!} + \frac{a^s}{s!} (c - s + 1) \right)^{-1} & \text{if } \rho = 1. \end{cases} \quad (10)$$

Note that letting $c \rightarrow \infty$ and restricting $\rho < 1$ in Equation (10) gives the steady-state probabilities of the $M/M/s$ system.

The mean performance parameters can be obtained by using Equations (9) and (10) and Little's Law [3]. The mean queue length can be obtained via the steady-state probabilities ($\rho \neq 1$)

$$L_q = \sum_{j=s+1}^c (j-s)p_j = \frac{p_0 a^s \rho}{s!} \frac{d}{d\rho} \left(\frac{1 - \rho^{c-s+1}}{1 - \rho} \right), \quad (11)$$

after applying L'Hospital's rule,

$$L_q = \frac{p_0 a^s \rho}{s!(1-\rho)^2} \left[1 - \rho^{c-s+1} - (1-\rho)(c-s+1)\rho(c-s) \right]. \quad (12)$$

For $\rho = 1$, it is necessary to apply L'Hospital's rule twice.

To obtain the other mean performance parameters, Little's formula can be used as in the $M/M/s$ system. However, customers who arrive to find c customers in the system are lost. Fortunately, for a system with Poisson arrivals, these arrivals see the time-averaged state of the system (PASTA, Poisson arrivals see time averages, property; see Wolff [4,5]). By PASTA, it follows that effective arrival rate seen by servers is $\lambda' \equiv \lambda(1 - p_c)$. Hence the mean time in the waiting line is $W_q = L_q/\lambda'$,

$$W_q = \frac{L_q}{\lambda(1 - p_c)}. \quad (13)$$

The mean number of customers in the system is

$$L = L_q + \frac{\lambda'}{\mu} = L_q + a(1 - p_c). \quad (14)$$

Finally, the mean time in the system is $W = L/\lambda'$:

$$W = \frac{L}{\lambda(1 - p_c)}. \quad (15)$$

The derivation of the c.d.f. of the delay time in the queue, $F_q(t)$, is a bit more complicated because of the finite series. The derivation can be found in Gross and Harris [3].

$$F_q(t) = 1 - \sum_{j=s}^{c-1} \frac{p_j}{1 - p_c} \sum_{i=0}^{j-s} \frac{(s\mu t)^i e^{-s\mu t}}{i!}. \quad (16)$$

In the next section, we discuss the well-known Erlang C formula which describes the probability that an arbitrary customer experiences delay in the $M/M/s$ system.

ERLANG C FORMULA

An important quantity is the probability that (in steady state) an arriving customer is delayed before receiving service. The PASTA property ensures that the steady-state probability that an arriving customer sees j customers in the system at arrival is given by p_j . Therefore, the steady-state probability that an arriving customer is delayed is $\sum_{j=s}^{\infty} p_j$. This probability, usually denoted by $C(s, a)$, is computed using the so-called *Erlang C formula* given by [2]

$$C(s, a) = \frac{\frac{a^s}{s!(1-\rho)}}{\sum_{i=0}^{s-1} \frac{a^i}{i!} + \frac{a^s}{s!(1-\rho)}}, \quad 0 < a < s. \quad (17)$$

Note that Equation (17) requires that $\rho < 1$ to ensure stability. The Erlang C formula is an important result in designing telecommunication systems, call centers, or service systems, especially to determine the number of trunks, agents, or customer service representatives for a specified desired probability of waiting.

Related to the Erlang C formula is the Erlang B formula, which gives the steady-state probability of blocking for the $M/G/s/s$ (Erlang loss) system (see *The M/G/s/s Queue*). Since there is no waiting space in that system, arriving customers who find all s servers busy are lost and do not return. The service times are assumed to be independent and identically distributed with a finite mean (not necessarily exponential). The Erlang B formula is given by [3]

$$B(s, a) \equiv p_s = \frac{a^s/s!}{\sum_{j=0}^s \frac{a^j}{j!}}. \quad (18)$$

Unlike the Erlang delay model, the Erlang loss model exhibits an *insensitivity* property, meaning that the blocking probability, $B(s, a)$, is independent of the service time distribution. By using a reciprocal analysis, one can easily show that there exists a simple relationship between the Erlang B and the

Erlang C formulae [2]

$$C(s, a) = \frac{sB(s, a)}{s - a[1 - B(s, a)]}, \quad 0 < a < s. \quad (19)$$

STRUCTURAL PROPERTIES AND COMPUTATIONAL ISSUES

Several structural properties of the function $C(s, a)$ have been extensively studied in the literature. The monotonicity of $C(s, a)$ in both a and s can be easily derived, where $C(s, a)$ is increasing in a , for a fixed s and decreasing in s , for a fixed a . Lee and Cohen [6] discussed the convexity of $C(s, a)$ as a function of the offered load, a . Additionally, a proof of the convexity of $C(s, a)$ in s is provided by Jagers and van Doorn [7].

For large a and s , it can be difficult to compute the delay probability because of the presence of factorials and potentially very large powers. However, the delay probability can be much more easily computed by using a recursive scheme. Specifically, using reciprocals, it is not difficult to show that $C(s, a)$ can be equivalently expressed by

$$C(s, a) = \frac{1}{1 + \frac{s-a}{a} \frac{s-1-aC(s-1, a)}{(s-1-a)C(s-1, a)}}, \quad s > a + 1. \quad (20)$$

Note that the Erlang C formula is defined for $a < s$, and, if we start the recursion from $C(1, a)$, we are restricted to $a < 1$, which makes the recursion less useful than the recursion for the Erlang B formula [2], which is

$$B(k, a) = \frac{aB(k-1, a)}{k + aB(k-1, a)}, \quad k = 1, 2, \dots, s, \quad (21)$$

where $B(0, a) \equiv 1$. However, we can use Equation (21) to obtain $B(s, a)$ and substitute in Equation (19) to obtain the delay probability. It is very easy to implement these recursions in a spreadsheet or a computer program to obtain the delay probability for a heavily loaded system with a very large

Figure 1. The probability of delay as a function of s when a is fixed.

number of servers. For example, Fig. 1 graphs the delay probability $C(s, a)$ as a function of the number of servers s when the offered load is fixed at $a = 1000$.

FURTHER READING

Some further details of the $M/M/s$ model can be found in many classical queueing textbooks including Cooper [2], Gross and Harris [3], Ross [8], and Wolff [5]. Important properties of the loss and delay formulae have been studied by many researchers. Lee and Cohen [6] discussed the convexity of $C(s, a)$ as a function of the offered load, a . Grassman [9] gives the proof of the convexity for the related performance parameters, the mean number of customers in the system L , and the mean number of customers in queue L_q . Jagers and van Doorn [7] proved the convexity of functions that generalize the Erlang loss and delay functions. Harel and Zipkin [10] proved strong convexity results for the average sojourn time in an $M/M/s$ system. Dyer and Proll [11] provided marginal analysis for allocating servers in $M/M/s$ queues. Harel [12] provided sharp bounds and simple approximations for the loss and delay formulae. Recently, Harel [13] improved the bounds [12], and obtained new bounds and simple approximations for the number of servers

that invert the Erlang delay and loss formulae. Additionally, it was shown that the steady-state idle probability is a convex and decreasing function of traffic intensity.

The extension of the model to general service times can be handled by approximation schemes that exist in the queueing literature. Kingman [14] provided heavy-traffic approximations for the $M/G/s$ queue. When s is very large, another asymptotic regime emerges, namely the quality and efficiency driven (QED) regime. Halfin and Whitt [15] were the first to analyze the $M/M/s$ queue in this regime, and they derived an asymptotic expression for the Erlang C formula. An important extension of the model, known as the *Erlang A Model*, allows for customer abandonment (i.e., customers who join the queue but may opt to leave the queue after some fixed or random time). Borst *et al.* [16], Halfin and Whitt [15] and Garnett *et al.* [17] each analyze the Erlang A model under different asymptotic regimes. Recently, Pang and Whitt [18] provided heavy-traffic extreme value limits for the Erlang delay model with abandonment. Gans *et al.* [19] provided an extensive review of call centers, which includes the Erlang delay and loss models. Additionally, Stidham [20] provided an extensive survey covering the analysis,

design, and control of a variety of queueing systems, including the $M/M/s$ queue.

THE MANUFACTURING AND SERVICE OPERATIONS MANAGEMENT (MSOM) SOCIETY

TAVA OLSEN
Department of Information Systems
and Operations Management,
University of Auckland Business
School, Auckland, New Zealand

OVERVIEW

The Manufacturing and Service Operations Management (MSOM) Society is one of the largest societies within the Institute for Operations Research and the Management Sciences (INFORMS) and its purpose statement reads as follows:

The *MSOM Society* promotes the enhancement and dissemination of knowledge, and the efficiency of industrial practice, related to the operations function in manufacturing and service enterprises. The methods which *MSOM* members apply in order to help the operations function add value to products and services, which are derived from a wide range of scientific fields, including operations research and management science, mathematics, economics, statistics, information systems, and artificial intelligence. The members of *MSOM* include researchers, educators, consultants, practitioners, and students, with backgrounds in these and other applied sciences.

Thus MSOM is the natural home for operations management (OM) research from a range of disciplines and approximately 950 people, particularly students and faculty from OM departments and groups, as well as from industrial engineering and operations research departments and groups, are the members. Although the society welcomes practitioners, they have traditionally been a small portion of the membership. The membership is primarily US-based, although there are a significant number of European and Asian members.

This article outlines the history and governance of the society, gives information on the society prizes and publications, and meeting information. Further details on the society may be found at <http://msom.society.informs.org/>.

HISTORY AND GOVERNANCE

MSOM began as a technical section of INFORMS following the 1995 merger of the Operations Research Society of America (ORSA) and The Institute of Management Sciences (TIMS). It was formed from a merger of the ORSA, Technical Section on Manufacturing Management (TECMAN), and the TIMS College on Production and Operations Management (COPOM). The outgoing chair of TECMAN was Candace Yano, although John Buzacott, TECMAN chair 1993–1994, was also highly involved in the formation of MSOM. COPOM appears to have been largely inactive at that time. Michael Magazine was the first official president of MSOM and served from 1995 to 1996. A complete listing of prior presidents may be found in the appendix. In 1997, under the presidency of Mark Spearman, MSOM transitioned to a society within INFORMS, with the transition becoming formal in 1998 and is now officially titled, the “Manufacturing and Service Operations Management Society: An INFORMS Organization.”

MSOM was founded with a president, president-elect, vice president (Meetings), and secretary/treasurer; all of these offices continue today. All offices involve a one-year term, voted on in the spring, traditionally with two candidates for each post although this is not required by the bylaws (http://msom.society.informs.org/pdf/MSOM_bylaws_Updated_may_9_08.pdf). The new officers take over at the end of the business meeting at the MSOM summer conference.

At the Society's founding, there was a newsletter and Frank Ciarallo served as the long-standing, and apparently only,

newsletter editor. He also served as webmaster and mailing list moderator for many years, both of which positions continue to this day, separately. Other volunteer position for MSOM include the INFORMS cluster organizer(s), the MSOM student paper competition coordinator, and the Society's representative on the Subdivisions Council.

One of the biggest changes to the Society's organization came in 2006 with the introduction of Special Interest Groups (SIGs) under the leadership of Gerard Cachon and Martin Lariviere. The initial SIGs were supply chain management and service management groups. These were quickly followed upon petition by iFORM, interface between Finance, Operations, and Risk Management. In 2009, the MSOM officers approved a fourth SIG: health care OM. The SIG chairs are officially officers in the Society. Finally, in 2009, MSOM initiated an official affiliation with the behavioral section of INFORMS, when they indicated that they were not interested in becoming SIG.

PRIZES AND PUBLICATIONS

A student paper competition was introduced at the time of the Society's founding and is now traditionally run during the summer. A distinguished service award was introduced in 1996. In 1999, the Society approved the appointment of Fellows, after the work of a committee chaired by Nicholas Hall. The first Fellows were appointed in 2000 and a complete list may be found in the appendix. From 2009, Fellows gave a presentation at the MSOM conference; previously, they had given a presentation at the INFORMS annual meeting. Details for applying for these prizes and a list of past recipients may be found at <http://www3.informs.org/index.php?c=35&kat=-+INFORMS+Subdivision+Prizes>

In 1997, Leroy Schwarz became the founding editor of the MSOM Journal. John Buzacott was awarded the 1998 MSOM distinguished service award in part because he was largely responsible for getting ORSA/TIMS/INFORMS to launch the new journal. The inaugural volume was published

in 1999 and from the beginning, has focused on high quality papers and short review cycles. In 2003, Garrett Van Ryzin took over as editor-in-chief, followed by Gerard Cachon in 2006–2008. Stephen Graves is the current editor-in-chief.

In 2007, Gerard Cachon instituted the MSOM Best Paper Award, an award for the best published work in the MSOM journal that has appeared in the past 3 years.

MEETINGS

The first unofficial MSOM meeting was actually a TECMAN meeting and was held in 1994 at Carnegie Mellon; it was coorganized by John Buzacott and Candi Yano. The first official meeting was held in 1996 at Dartmouth College and was organized by Medini Singh. These meetings had published proceedings, a practice continued until the 2000 meeting at the University of Michigan, where the proceeding were made electronic and then made optional at the 2002 meeting at Cornell. Proceedings were then brought back in 2006 by Georgia Tech and made to be refereed as a Method of Screening Articles. The conference has always been held at a university campus and a complete list of locations with dates may be found in the appendix.

The MSOM meeting started as a biannual meeting and then moved to an annual meeting when INFORMS turned its spring meeting from a general meeting to a practitioners' meeting. It is typically held in late June and the society bylaws state "The Conference shall be held no earlier than the second week of June and no later than the third week of July. Deviation from this timing requires the approval of a majority of Society officers." Until 2008, it was preceded by the one-day Multiechelon Inventory Conference, an annual conference unaffiliated with any particular society. When the MSOM conference was biannual, the Multiechelon Inventory Conference was held by itself in the off years. In 2008, the decision was made to replace the Multiechelon Inventory Conference with one-day parallel SIG conferences, to typically precede the MSOM conference.

Refereed proceedings as a part of the conference have been somewhat controversial and the subject of a number of discussions at MSOM business meetings. However, in this author's opinion, the general consensus appears to be (i) members like the meetings to be held at universities; (ii) members do not like too many parallel tracks (which are also often impractical given university facilities); and (iii) members like the meeting length to be the traditional 2 days. These constraints, along with the growing size of the conference (from 80–90 attendees in 1994 to around 340 in 2009), have meant that screening of papers for acceptance to the conference has become a somewhat accepted practice, although the precise format is still under discussion and was the subject of a 2008 sub-committee whose recommendations will be implemented in 2010.

A call for hosting the conference is typically put out by the VP (Meetings) around November/December for the conference that is 2.5 years away so that conferences are determined 2 years in advance. There is also an informal rotation that the MSOM conference is held internationally once in every 3 years, although this is not formally stated anywhere. There has also been a rotation for these international conferences between east and west of the United States, although there has actually been only one international eastern conference, which was in Beijing, China, in 2007.

The Society also sponsors tracks at the fall INFORMS meeting and at other conference (e.g., CORS-INFORMS, Euro-INFORMS, International Meeting of INFORMS, IFORS etc) on an *ad hoc* basis. At the fall INFORMS meeting, each SIG hosts a track in addition to the general track. Business meetings are held both at the fall INFORMS conference and at the summer conference. Minutes are taken and posted to the MSOM website, after the meeting (<http://msom.society.informs.org/minutes/>).

SUMMARY

As one of the largest societies within INFORMS, MSOM is a healthy and thriving society. It offers a range of prizes, has a top

quality journal, and is financially healthy. In this author's opinion, its main challenge is to remain the primary home for OM research as new OM topics grow and desire communities. The addition of SIGs has helped alleviate this problem to some extent and yet, it has also introduced some new questions. For example, what is the precise relationship between the Health Care OM SIG and the Health Care Applications section within INFORMS? This is an open question yet to be developed further. Further, MSOM currently has no formal relationship with the POM Society (<http://www.poms.org/>) and yet both are growing societies competing for similar membership bases; at some point, it may make sense for the two societies to either form a closer relationship or more clearly differentiate themselves. These will be topics that are likely to occupy the minds of future MSOM presidents.

THE $M/G/\infty$ QUEUE

NATARAJAN GAUTAM

Department of Industrial and Systems
Engineering, Texas A&M University,
College Station, Texas

An $M/G/\infty$ queue is one where the arrivals are according to a Poisson Process, and the service time for each arriving entity is generally distributed with cumulative distribution function (CDF) $G(\cdot)$. Further, there are an infinite number of servers in the system, and therefore the sojourn time in the system equals the service time. Let λ be the average arrival rate. Also, let τ denote the mean service time. We will typically consider the mean service time to be finite, that is, $\tau < \infty$. Also, for nontriviality we assume $\tau > 0$. It is crucial to note that there is no restriction in terms of the service time random variable; it could be discrete, continuous, or a mixture of discrete and continuous.

The first time anyone hears about the $M/G/\infty$ queue, the biggest concern is the issue of infinite number of servers. It does not seem practical and if it is a purely theoretical exercise, why bother? Several reasons come to mind. There are systems where infinite servers are excellent approximations, such as conveyor belts where for all practical purposes the entities on the conveyor belt can begin service as soon as they arrive. Similarly systems with *self-service* can also be modeled as $M/G/\infty$ queues. A more common approximation is when the number of servers in an $M/G/c$ queue is large and the traffic intensity is not too high (i.e., not almost 1). Typically, the $M/G/c$ queue for $c > 1$ is difficult to analyze. Hence, the $M/G/\infty$ queue is also known as a *queue with Poisson arrivals and ample servers*.

Other motivations for studying $M/G/\infty$ queues are to obtain insights into the model and analysis that can be used in related systems. For example, to explain some of the results of $M/G/c/c$ queues, one typically turns to $M/G/\infty$ results. Moreover, among

all the systems where the arrival or service (or both) is nonexponential, $M/G/\infty$ is the only one that can be analyzed for transient behavior, departures from queues, and time-varying parameters. These reasons are usually sufficient to make a case to teach $M/G/\infty$ in courses and also include in textbooks (and encyclopedias).

Recently, there have been some renewed interest and new results for $M/G/\infty$ while being applied to modeling traffic in computer-communication systems. Parulekar and Makowski [1] considered a slotted-time system, where the arrivals in a given slot were proportional to the number in the system of an $M/G/\infty$ queue with heavy tail service time (such as a Pareto distribution). Notice that since the number in the system for an $M/G/\infty$ is correlated over time, using a Pareto distribution results in long-range dependence, which is shown to be satisfied in traffic in computer-communication systems. Chang [2] characterizes such an arrival process using large-deviations theory to obtain the tail distribution of subsequent buffers.

Further, Likhanov and Mazumdar [3] as well as Resnick and Samorodnitsky [4] extend the slotted (or discrete time) version developed by Parulekar and Makowski [1] to the continuous time case. In particular, requests arrive according to a Poisson process and every request is responded by a heavy-tailed response, where fluid is poured at a constant rate. These are excellent models for web servers where information flows out (response) to requests that arrive according to a Poisson process and file sizes are heavy tailed. These are referred to as *fluid- $M/G/\infty$ queues*. In summary, the $M/G/\infty$ queue can be used to suitably approximate a number of applications, and there is a need to understand them in order to obtain useful insights.

Having motivated the need to study $M/G/\infty$ queues, here is how the remainder of this article is organized. In the section titled "Number in System: Transient and

Steady State,” we describe transient and steady-state analysis of the number in the system. We use those results to derive the busy period distribution in the section titled “Busy Period Distribution.” Then in the section titled “Departure Process: Transient and Steady State,” we study the departures from $M/G/\infty$ queues. We consider an extension to the standard $M/G/\infty$ system by allowing time-varying arrivals in the section titled “Time-varying Arrivals: $M_t/G/\infty$.”

NUMBER IN SYSTEM: TRANSIENT AND STEADY STATE

Consider an $M/G/\infty$ queue having independent and identically distributed service times with CDF $G(\cdot)$. Let $\{N(t), t \geq 0\}$ be a Poisson process with parameter λ that counts the number of arrivals in time $(0, t]$ for all $t \geq 0$. Define $X(t)$ as the number (of entities) in the system at time t . The objective of transient and steady-state analysis is to obtain a probability distribution of $X(t)$ for finite t and as $t \rightarrow \infty$, respectively. We would first present the transient analysis and then take the limit for steady-state analysis.

Transient analysis typically depends on the initial state of the queue. To obtain simple closed-form expressions, we need to make one of the following three assumptions: (i) the queue is empty at $t = 0$, that is, $X(0) = 0$; (ii) the queue started empty in the distant past, that is, $X(-\infty) = 0$, and hence the stochastic process $\{X(t), t \geq 0\}$ is stationary; (iii) if $X(0) > 0$, then the service for all the $X(0)$ entities *begins* at $t = 0$. If one of the above three assumptions is not satisfied, we will have to know the times when service began for each of the $X(0)$ customers in order to obtain a distribution for $X(t)$.

For the transient analysis here, we make the first assumption, that is, $X(0) = 0$. Hence, we are interested in computing $p_j(t)$ defined as

$$p_j(t) = P\{X(t) = j | X(0) = 0\}.$$

Note that if we made the second assumption, then $X(t)$ would be according to the steady-state distribution for all $t \geq 0$. However, if we

made the third assumption, then

$$\begin{aligned} P\{X(t) = j | X(0) = i, B_i\} \\ = \sum_{k=0}^{\min(i,j)} \binom{i}{k} [1 - G(t)]^k [G(t)]^{i-k} p_{j-k}(t), \end{aligned}$$

with the event B_i denoting that service for all i initial customers begins at $t = 0$. Since this is straightforward, once $p_j(t)$ is known, we continue with obtaining $p_j(t)$ by making the first assumption.

Notice that $\{X(t), t \geq 0\}$ is a regenerative process with regeneration epochs corresponding to when the queueing system becomes empty. To obtain $p_j(t)$, consider an arbitrary arrival at time x such that $x \leq t$. Let q_x be the probability that this arriving entity is in the system at time t . Clearly,

$$q_x = 1 - G(t - x)$$

since it is the probability that this entity's service time is larger than $t - x$. Now consider a nonhomogeneous Bernoulli splitting of the Poisson (arrival) process $\{N(t), t \geq 0\}$ such that with probability q_x an entity arriving at time x will be included in the split process. Since the split process counts the number in the $M/G/\infty$ system at time t , we have

$$p_j(t) = \exp \left\{ -\lambda \int_0^t q_x dx \right\} \frac{\left\{ \lambda \int_0^t q_x dx \right\}^j}{j!}.$$

The proof is described in Kulkarni [5], Gross and Harris [6], and Wolff [7]. It is based on conditioning the number of arrivals in time t and using the fact that each of the given arrivals occurs uniformly in $[0, t]$. The argument is similar to the derivation of the number of departures from the $M/G/\infty$ queue in time t in the section titled “Departure Process: Transient and Steady State.”

Next, we write down $p_j(t)$ in terms of entities given in the model, namely, λ and $G(t)$. As a result of using $q_x = 1 - G(t - x)$ and change

of variables, we get

$$\begin{aligned}
 p_j(t) &= \exp \left\{ -\lambda \int_0^t q_x \, dx \right\} \frac{\left\{ \lambda \int_0^t q_x \, dx \right\}^j}{j!} \\
 &= \exp \left\{ -\lambda \int_0^t [1 - G(t-x)] \, dx \right\} \\
 &\quad \times \frac{\left\{ \lambda \int_0^t [1 - G(t-x)] \, dx \right\}^j}{j!} \\
 &= \exp \left\{ -\lambda \int_0^t [1 - G(u)] \, du \right\} \\
 &\quad \times \frac{\left\{ \lambda \int_0^t [1 - G(u)] \, du \right\}^j}{j!}.
 \end{aligned}$$

Using $p_j(t)$ we can also obtain

$$E[X(t)] = \lambda \int_0^t [1 - G(u)] \, du$$

and

$$\text{Var}[X(t)] = \lambda \int_0^t [1 - G(u)] \, du$$

by observing that for a given t , $X(t)$ is a Poisson random variable with parameter $\lambda \int_0^t [1 - G(u)] \, du$.

For the steady-state analysis, we let $t \rightarrow \infty$ in the transient analysis to derive all results. Let $X(t)$ converge in distribution to X as $t \rightarrow \infty$ such that $p_j(t) \rightarrow p_j$ where $p_j = \lim_{t \rightarrow \infty} P\{X(t) = j\}$. Taking the limit $t \rightarrow \infty$ for $p_j(t)$, we find

$$p_j = e^{-\lambda\tau} \frac{(\lambda\tau)^j}{j!},$$

where τ is the average service time. Then, with an integration-by-parts step it can be shown that

$$\tau = \int_0^\infty [1 - G(u)] \, du.$$

In addition, the mean and variance of the number in the system in steady state are both $\lambda\tau$ since X is a Poisson random variable with parameter $\lambda\tau$. Note that the mean

and variance of the sojourn times correspond, respectively, to the mean and variance of the service times since there is no waiting for service to begin. Before concluding this section, it is worthwhile observing that the steady-state probability p_j is identical to those of the $M/M/\infty$ system, and thus p_j does not depend on the CDF $G(\cdot)$ but just the mean service time.

BUSY PERIOD DISTRIBUTION

As we described earlier, $\{X(t), t \geq 0\}$ is a regenerative process with regeneration epochs corresponding to times when the number in the system goes from 1 to 0. Each regeneration time corresponds to one idle period followed by one *busy period* (time when there are one or more entities in the $M/G/\infty$ system). Let U be the regeneration time and $U = I + B$, where the idle time $I \sim \exp(\lambda)$ (i.e., time for next arrival in a Poisson process), and the busy period B has a CDF $H(\cdot)$. We need to determine $H(\cdot)$. For that we develop the following explanation based on Example 8.17 in Kulkarni [5].

Let $F(\cdot)$ be the CDF of U . Using a renewal argument by conditioning on $U = u$, we can write down a renewal-type equation for $p_0(t) = P\{X(t) = 0 | X(0) = 0\}$ as

$$\begin{aligned}
 p_0(t) &= \int_0^t p_0(t-u) \, dF(u) \\
 &\quad + \int_t^\infty P\{I > t | U = u\} \, dF(u).
 \end{aligned}$$

Since $U = I + B$, $P\{I > t | U = u\} = 0$ if $u \leq t$, we can rewrite

$$\begin{aligned}
 p_0(t) &= \int_0^t p_0(t-u) \, dF(u) \\
 &\quad + \int_0^\infty P\{I > t | U = u\} \, dF(u) \\
 &= \int_0^t p_0(t-u) \, dF(u) + P\{I > t\} \\
 &= p_0 * F(t) + e^{-\lambda t}
 \end{aligned}$$

with $p_0 * F(t)$ being the standard convolution notation.

We already have an expression for $p_0(t)$ in the section titled “Number in System: Transient and Steady State” as

$$p_0(t) = \exp \left\{ -\lambda \int_0^t [1 - G(u)] du \right\},$$

where $G(\cdot)$ is the CDF of the service times. One way to obtain the unknown $F(t)$ function is to numerically solve for $F(t)$ in $p_0(t) = p_0 * F(t) + e^{-\lambda t}$ and similarly solve another convolution equation to get $H(t)$. An alternate approach, typically standard when there are convolutions, is to use transforms. We consider the Laplace Stieltjes transform (LST) which is denoted as $\tilde{R}(s)$ for any positive-valued nondecreasing function $R(t)$ and is defined as

$$\tilde{R}(s) = \int_0^\infty e^{-st} dR(t).$$

Therefore, taking the LST on both sides of the equation $p_0(t) = p_0 * F(t) + e^{-\lambda t}$, we get

$$\tilde{p}_0(s) = \tilde{p}_0(s)\tilde{F}(s) + \frac{s}{s + \lambda}.$$

However, since we are ultimately interested in $H(t)$, we use the relation

$$\tilde{F}(s) = \left(\frac{\lambda}{\lambda + s} \right) \tilde{H}(s)$$

to obtain

$$\tilde{H}(s) = 1 + \frac{s}{\lambda} - \frac{s}{\lambda \tilde{p}_0(s)}.$$

In the most general case, the above LST is not easy to invert and obtain $H(t)$. Another challenge is to obtain $\tilde{p}_0(s)$ from $p_0(t)$, which is not trivial. However, there are several software packages available (such as Matlab and Mathematica) that can be used to numerically compute as well as invert LSTs.

Having said that, it is relatively straightforward to obtain $E[B]$, the mean busy period. Using the fact that $\tilde{p}_0(0) = p_0(\infty) = e^{-\lambda \tau}$, we can obtain

$$E[B] = -\tilde{H}'(0) = \frac{e^{\lambda \tau} - 1}{\lambda}.$$

Another way to obtain it is to use regenerative process results and solve for $E[B]$ in $1 - p_0 = \frac{E[B]}{E[B] + 1/\lambda}$.

DEPARTURE PROCESS: TRANSIENT AND STEADY STATE

Since the output from an $M/G/\infty$ may flow into some other queue, it is critical to analyze the departure process. Let $D(t)$ be the number of departures from the $M/G/\infty$ system in time $[0, t]$ given that $X(0) = 0$. For any arbitrary t , we seek to obtain the distribution of the random variable $D(t)$ and thereby characterize the stochastic process $\{D(t), t \geq 0\}$. Similar to the analysis for the number in the system, here too we first consider transient and then describe steady-state results. The results follow the analysis in Gross and Harris [6]. However, it is crucial to point out that there are many other elegant ways of analyzing departures from $M/G/\infty$ queues and extending them, some of which we will see toward the end of this section.

If we are given that n arrivals occurred in time $[0, t]$, then using the standard Poisson process results we know that the time of arrival of any of the n arrivals is uniformly distributed over $[0, t]$ and it is independent of the time of other arrival times. Therefore, consider one of the n arrivals that occurred in time $[0, t]$. The probability $\theta(t)$ that this entity would have departed before time t can be obtained by conditioning on the time of arrival and unconditioning as

$$\theta(t) = \frac{1}{t} \int_0^t G(t - x) dx = \frac{1}{t} \int_0^t G(u) du.$$

In addition, the probability that out of the n arrivals in time $[0, t]$, exactly i of those departed before time t is $\binom{n}{i} [\theta(t)]^i [1 - \theta(t)]^{n-i}$.

Now, to compute the distribution of $D(t)$, we condition on $N(t)$, which is the number of arrivals in time $[0, t]$. In order to remind us that we do make the assumption that $X(0) = 0$, we include this condition in the expressions. Therefore, we have

$$\begin{aligned} P\{D(t) = i | X(0) = 0\} &= \sum_{n=i}^{\infty} P\{D(t) = i | N(t) = n, X(0) = 0\} e^{-\lambda t} \frac{(\lambda t)^n}{n!} \\ &= \sum_{n=i}^{\infty} \binom{n}{i} [\theta(t)]^i [1 - \theta(t)]^{n-i} e^{-\lambda t} \frac{(\lambda t)^n}{n!} \end{aligned}$$

$$\begin{aligned}
&= \frac{[\theta(t)]^i}{i!} e^{-\lambda t} (\lambda t)^i \sum_{n=i}^{\infty} [1 - \theta(t)]^{n-i} \frac{(\lambda t)^{n-i}}{(n-i)!} \\
&= \frac{[\lambda t \theta(t)]^i}{i!} e^{-\lambda t \theta(t)}.
\end{aligned}$$

Therefore, for a given t , $D(t)$ is a Poisson random variable with parameter $\lambda t \theta(t)$. In other words, the transient distribution of the number of departures in time t is Poisson with parameter $\lambda t \theta(t)$. Having described the transient analysis, we just let $t \rightarrow \infty$ for steady-state analysis.

It can be shown from the definition of $\theta(t)$ that for very large t , $t\theta(t)$ approaches $t - \tau$. However, since we assume that τ is finite, as we let $t \rightarrow \infty$, the departure becomes a Poisson process with parameter $\lambda(1 - \tau/t) \rightarrow \lambda$. Of course, we have not shown stationary and independence properties of the departure process; the reader is encouraged to refer to Serfozo [8, Section 9.6] for a derivation based on stationary marked point processes. Using the above results, as well as stationary and independence properties, we can conclude that the departure process from an $M/G/\infty$ queue in steady state is the same as the arrival process, that is, a Poisson process with parameter λ . Further, similar to the steady-state probability p_j being identical to that of the $M/M/\infty$ system and being independent of the CDF $G(\cdot)$, the departure process in steady state is also identical to that of the $M/M/\infty$ system and depends only on the mean service time (τ) and not on its distribution.

We conclude this section by emphasizing that there is substantial amount of research on departure process from an $M/G/\infty$ queue that has not been covered here. Daley [9] shows that the departure process when viewed as a random translation of the arrival process is Poisson. That argument even works in the nonhomogeneous case (i.e., the $M_t/G/\infty$ described in the next section). Also, a natural extension of output processes is to consider a network of $M/G/\infty$ queues. Analyzing a network of feedforward $M/G/\infty$ queues is particularly straightforward leveraging upon the fact that the output of an $M/G/\infty$ queue is also Poisson. For non-feedforward networks (i.e., networks

with cycles) some of the properties are more tricky to show, and the reader is referred to Serfozo [8]. Furthermore, it can be shown that (see Kobayashi and Mark [10]) the $M/G/\infty$ queue is quasi-reversible and hence useful in analyzing networks (e.g., to obtain product-form solutions).

TIME-VARYING ARRIVALS: $M_t/G/\infty$

In this section, we consider an extension to the $M/G/\infty$ queue. The arrival process is Poisson; however, the parameter of the Poisson process is time varying. The average arrival rate at time t (for all t in $(-\infty, \infty)$) is a deterministic function of t represented as $\lambda(t)$. Hence, the arrival process is defined as a nonhomogeneous Poisson process. Everything else is the same as the regular $M/G/\infty$ queue. We call such a system an $M_t/G/\infty$ queue. This summary of results for the $M_t/G/\infty$ queue is based on Eick *et al.* [11].

Recall that we need to make one of the three assumptions stated in the section titled “Number in System: Transient and Steady State,” otherwise we would need to know when service started for each of the customers at a reference time, say $t = 0$. We make the second assumption, although making one of the other two would not significantly alter the analysis but the results would not be as neat. In other words, assume that the system was empty at $t = -\infty$. Assume that for all finite t , $\lambda(t)$ is nonnegative, measurable, and integrable. With these assumptions in mind, we state the results.

The results are in terms of the equilibrium random variable of the service times. In particular, let S be a random variable corresponding to a service time. We have already defined the CDF $G(x) = P\{S \leq x\}$ and mean $\tau = E[S]$. The equilibrium random variable S_e corresponding to the service times has a CDF $G_e(x)$ defined as

$$G_e(x) = P\{S_e \leq x\} = \frac{1}{\tau} \int_0^x [1 - G(u)] du.$$

One encounters equilibrium random variables in renewal theory. If a renewal process with inter-renewal random variable Y starts

at $t = -\infty$, then at time $t = 0$, the remaining time for a renewal is according to Y_e .

Recall the notation $X(t)$. Here, it denotes the number (of entities) in the $M_t/G/\infty$ system at time t . Then for any t , $X(t)$ has a Poisson distribution with parameter $\mu(t)$ given by

$$\mu(t) = E[\lambda(t - S_e)]E[S]$$

with $E[X(t)] = \text{Var}[X(t)] = \mu(t)$. It is important to note that $\lambda(\cdot)$ is the function defined in this section and not make the mistake of thinking that at $t = 0$ the average number in the system is negative! In fact, observe that the number in the system at any time depends on the arrival rate S_e time units ago. Further, the departure process also has a similar time lag effect where the average departure rate at time t is $E[\lambda(t - S)]$ and the resulting process is nonhomogeneous Poisson.

For $u > 0$ and any t ,

$$\begin{aligned} \text{Cov}[X(t), X(t + u)] \\ = E[\lambda(t - (S - u)_e^+)]E[(S - u)^+], \end{aligned}$$

where the notation $(y)^+$ is $\max(y, 0)$. In fact, this result can be derived for the homogeneous case (which we have not done earlier, but is extremely useful especially in computer-communication traffic with long-range dependence). For an $M/G/\infty$ queue where $\lambda(t) = \lambda$,

$$\text{Cov}[X(t), X(t + u)] = \lambda P\{S_e > u\}E[S].$$

There are several results for networks of $M_t/G/\infty$ queues. Since the entities do not interact and departure processes are Poisson,

the analysis is fairly convenient. The reader is referred to Eick *et al.* [11] as well as the references therein for further results.

THE NASCENT INDUSTRY OF ELECTRIC VEHICLES

DIEGO KLABJAN

TIMOTHY SWEDA

Department of Industrial Engineering
and Management Sciences,
Northwestern University,
Evanston, Illinois

INTRODUCTION

Although electric vehicle (EV) technology has existed since the mid-1800s, gasoline-powered automobiles with internal combustion have largely overshadowed EVs because of their lower costs, higher speeds, and greater driving ranges. Consequently, public interest in EVs has remained low until recently, when the 2000s' energy crisis and subsequent recession sparked consumer demand for sustainable transportation. This heightened interest is not transient. As automakers race to bring mass-produced consumer EVs to market and policy makers provide incentives for both the producers and end users of these vehicles, the public's attitude toward sustainable transportation will be solidified as EV adoption rates increase.

To encourage adoption of EVs, public and private sector organizations are teaming up to provide charging infrastructure at both the local and national levels. In addition to the United States, other countries such as Canada, Australia, Denmark, Israel, China, and Japan have begun laying the groundwork for new EV fleets [1]. The teams responsible for such infrastructure seek to maximize the convenience of owning and operating an EV, and through collaboration with power utility companies, they can ensure the reliability and energy efficiency of their systems.

The time is ripe to begin planning for the rollout of EVs and their supporting

infrastructure, and research opportunities abound for those versed in analytics and operations research. In this article, the features of EVs which distinguish them from the ubiquitous gasoline-powered vehicles are outlined, and the various types of charging infrastructure are described. A series of open issues to be addressed by operations researchers is also presented to demonstrate the vast potential for new research and to map out future paths of study.

WHAT IS AN EV?

An EV is a vehicle that operates solely using electricity. It has an electric motor and stores energy in an internal battery, which can be recharged by plugging the vehicle into an outlet or charger. Because EVs do not use any gasoline, they are also known as zero-emission vehicles since they do not produce tailpipe emissions. Indirectly, though, they are responsible for a share of the greenhouse gases emitted by the coal-burning generators which produce the electricity for their operation, but the net carbon footprint of an EV is still less than that of a comparable gasoline-powered vehicle [2].

One major concern with EVs is their limited driving range as compared with regular gasoline-powered vehicles. This factor increases the likelihood of running out of charge while on the road, and because recharging can take several hours at standard voltages, the inconvenience to a stranded driver is significant. For this reason, some drivers prefer the concept of a plug in hybrid EV (PHEV). PHEVs retain most of the same traits as pure EVs, but they also utilize an internal combustion engine fueled by gasoline. Depending on the make, a PHEV may either maximize overall energy efficiency by reverting to its all-electric mode for city driving and switching to gasoline power for highway driving, or minimize gasoline usage by utilizing the combustion engine only after the battery is depleted.

Hybrid electric vehicles (HEVs), which have gained popularity over the last several years, differ from PHEVs because they have no external outlet and thus cannot draw power from the electrical grid. Instead, their electric power comes from an internal generator driven by the combustion engine, or is restored via regenerative braking, in which kinetic energy from deceleration is recaptured rather than dissipated as heat. While this characteristic does offer improved fuel efficiency over regular vehicles, the efficiency is still less than that provided by PHEVs and pure EVs [3].

INFRASTRUCTURE REQUIREMENTS

The key feature of EVs is their ability to connect to the electrical grid. In order for them to experience widespread adoption by the public, they must be able to connect to the grid efficiently and effortlessly, and operations research can aid in the development of solutions for accomplishing this goal. The three main types of EV charging infrastructure include at-home charging methods, public charging stations, and battery swapping concepts.

At-Home Charging

Currently, EV charging takes place almost exclusively in private garages, which are expected to continue to be the primary charging location as EVs gain popularity. Therefore, it is important for at-home charging solutions to be as convenient and reliable as possible.

The most common method of charging EVs at home is by conventional (Level I) charging. It involves plugging an EV into a standard 120 V wall socket. Charging the battery completely can take approximately 8–14 hours [4]. This solution suffices for the majority of EV owners since they can plug in their vehicle at the end of the day, let it charge overnight, and wake up the next morning to a fully charged vehicle. The system also works for the power companies because charging takes place during off-peak hours when demand for electric power is low. For drivers hoping to

get the most mileage out of their EVs, however, the long time required for a complete recharge is a serious drawback. Once the battery is fully depleted, the vehicle is effectively out of commission until the following day.

An alternative to Level I charging has been termed *opportunity charging*, or Level II charging, which is designed to fully recharge EV batteries in 4 hours or less [4]. To achieve the faster charging time, the outlet voltage is increased to around 240 V. Level II charging is intended to extend the daily mileage of EVs by allowing a greater number of excursions per day, since drivers can plug in their vehicles during meals or other downtime and make another trip only hours later. Given that very few drivers return home with a fully depleted battery, the actual time necessary to recharge can be much less than 4 hours if the battery still carries a partial charge. This also extends the length of outings occurring later in the day because drivers do not need to worry about limiting their range due to a partially depleted battery.

Several different pricing models for the electric power used to fuel EVs have been considered. Currently, EV owners who charge their vehicles at home pay for electric power in the same way that they do for power used by other appliances. A feasible alternative would be to meter electricity used by EVs separately, either within at-home charging units or on-board the vehicles themselves, and charge a different rate for EV electricity usage. Some studies have examined the effects of imposing a per-mile tax on gasoline-powered vehicles as opposed to a per-gallon tax [5,6], and a similar pricing mechanism could be considered for EVs.

Dynamic pricing schemes may be necessary to attenuate peak loading on the electrical grid. Some research has already been done to study the impact of EV charging on the grid [7–9], and consideration of time of use pricing, critical peak pricing, and nodal pricing will help the utility companies to optimize loading on their systems. Empirical research on managing EV charging behavior will become important as EV adoption rates rise and more data becomes available.

Public Charging

Despite the importance of at-home charging, the ability to recharge EVs while away from home will be critical to their success. PHEVs will still be able to utilize the existing network of gasoline stations in case their batteries become depleted while on the road, but pure EVs will need to be able to access the grid wherever they are. This will allow EV drivers to commute both short and long distances without needing to own a spare, gasoline-powered (or hybrid) vehicle.

So far, only a handful of charging stations in the United States have been installed and made accessible to the public, and their primary purpose is to generate publicity, spread awareness, and encourage the use of EVs. They are centrally located at sites such as community centers and major-chain supermarkets, but the eventual goal is to have one charging station per parking spot rather than one station per site. As the rate of EV ownership increases, multiple drivers will want to plug in and charge their vehicles at the same time. One way to accomplish this is by outfitting parking lots and garages with sufficient charging infrastructure so that drivers can plug into the grid wherever they park.

It is expected that most drivers who plug in away from home will be working, shopping, or participating in some other activity that will last only a few hours. Therefore, Level II charging capability will likely be the standard for public charging stations. For drivers in need of a more expedited recharge, however, Level II charging may be insufficient. Level III charging, which requires less than 10 minutes for a full recharge (approximately the same amount of time necessary to fill a tank with gasoline) [4], is instead seen as a viable solution for when time is of the essence. It remains to be seen whether Level II or Level III charging will be most popular among EV drivers, but it seems certain that a mix of the two will persist since both types have their advantages (Type III is faster, but Type II requires lower voltages and less specialized hardware).

An open area of research for operations researchers is the pricing of charging services. Previous studies on gasoline station pricing provide a starting point [10,11], but

the fact that electricity is a utility (and, thus, is regulated) poses new challenges. Currently, EV drivers must first purchase a membership in order to utilize a company's public charging stations, and then they are required to purchase a subscription plan. Subscribers can pay as they go (i.e., pay a flat fee each time they recharge), purchase a monthly or annual quota, or buy an unlimited plan that allows them to recharge as frequently as they wish. In each case, the number of recharges is measured by the number of times an EV is plugged in and unplugged. An alternative to consider would be metered charging, where rates are determined by the amount of power used rather than the total number of recharges. This option would appeal to drivers who do not deplete their batteries before recharging and require only a partial recharge. Furthermore, studies examining the effects of regulation on charging service providers would aid in determining whether or not these companies should be treated as utilities, as they sell electric power yet do not constitute a power plant.

Demand modeling is necessary to better understand pricing models of EVs and charging stations. A consumer's decision of whether or not to purchase an EV depends heavily on the cost and convenience of recharging. If recharging is expensive or if charging stations are inconveniently located, a highly priced EV will be difficult to sell. In addition, social networks may play a role in vehicle purchasing decisions, as buyers may be more likely to purchase EVs if their friends also own EVs. Knowing how all of these factors influence individuals' attitudes toward EVs and, ultimately, their decision to purchase (or not to purchase) an EV will be instrumental in determining the optimal pricing of EVs and charging stations.

Discrete choice modeling, a popular and widely accepted technique in transportation demand modeling, is a natural fit to model the demand for EVs. It has already been used in several studies examining the demand for EVs [12–14], but further research using more recent data will be required as the public becomes more informed about EVs. Predictive models that capture trends in the

demand for EVs will also be necessary to fully understand the EV market.

Battery Swapping Stations

An alternative to Level III charging stations is battery swapping stations. Rather than recharge the battery, an EV driver can simply swap a depleted battery for a fully charged one. The process is not only slightly faster than recharging, but it is also fully automated. It has already been successfully tested in Japan, and takes less than one minute from beginning to end [15].

Unlike charging stations, which have minimal spatial requirements and can be installed in home garages or parking spaces, battery swapping stations are comparable to gasoline stations and thus need dedicated plots of land. The capital costs of acquiring the land, constructing a facility, and maintaining an inventory of batteries are much greater than the cost of installing a charging station; thus, swapping stations will be less prevalent than charging stations, especially during the early phases of EV adoption. Before battery swapping stations are made available to the public, their primary users will be companies that operate large EV fleets, such as taxi, shuttle, and delivery services.

Battery swapping has a number of issues that are yet to be resolved. In order to ensure that a driver is able to swap batteries, there must be a sufficient number of charged batteries in the inventory. Because of the spatial requirements needed for storing EV batteries, it is neither practical nor cost effective to carry a large surplus. On the other hand, it would be unacceptable for a driver to be unable to swap for a fully charged battery. The number of chargers at the station for recharging depleted batteries would also need to be kept within a reasonable level to satisfy service requirements without incurring excessive cost. In addition since batteries have a limited lifetime (measured in charging cycles), a swapping station would need to manage its inventory by recycling or discarding worn out batteries and replacing them with newer ones. This task is complicated by the fact that the station has little control over the incoming stock of depleted

batteries. Some sort of safeguard would need to be established to protect the station from handling too many incoming batteries that have reached the end of their lifetime.

If a swapping station decides to recycle its used batteries, it faces the decision of when to withdraw those batteries from its inventory. A used battery has salvage value because it can still store electric charge, enough for some applications beyond EVs, although this value decreases with the age of the battery. Similarly, the swapping station may choose to purchase used batteries to replace the stock it recycles, especially since these batteries will eventually be swapped out with incoming ones. Determining the appropriate purchasing price of a used battery is yet another optimization problem to solve.

Since a proof-of-concept of battery swapping for EVs was only recently demonstrated, the literature is barren with regard to optimal swapping station management. A team from Japan has used queueing systems to analyze the operation of a single swapping station [16], but their model relies on simplistic assumptions (such as Poisson arrival and processing times) and does not take into account the presence of other battery swapping stations. Further research utilizing more sophisticated modeling techniques with more realistic assumptions is warranted.

Smart Grid Applications

The future of the EV infrastructure will be greatly enhanced by the development of the smart grid for delivering electric power to consumers. Presently, most power distribution systems provide electric power to customers without any control to curtail wasteful usage or to reallocate unnecessary peak-hour consumption to off-peak hours. (A few systems and utilities do employ real-time controls and time of use pricing [17–19], but these efforts are still in their infancy.) By incorporating such controls into their systems, power utility companies can better match supply and demand, thereby reducing costs, conserving energy, and improving reliability. The ability to optimize distribution in real-time is especially important when utilizing renewable

energy sources, such as wind and solar, which are intermittent.

EV charging would directly benefit from the presence of the smart grid. For drivers who charge their EVs overnight, the smart grid would ensure that the cost of recharging would be minimized by delaying charging until off-peak hours. Collecting data on a driver's driving activity and patterns would permit an even greater degree of charging optimization, especially for Level II charging, which is more likely to occur during peak hours. For example, if a driver's daily commuting distance is 30 miles and the EV's battery has enough charge left for 20 miles, the smart grid might decide to only recharge a portion of the battery—enough for the driver to return home, plus a buffer—and then complete the remainder of the recharge later during off-peak hours. There could always be manual overrides, of course, if the driver plans to deviate from his or her normal activities, but intelligent recharging would benefit both the power company and the customer.

As much as the smart grid could optimize energy distribution, the addition of vehicle-to-grid (V2G) technology would improve the efficiency of the grid even more. With V2G, not only can the grid provide power to EVs and other electrical appliances, but the EVs can also provide power back to the grid. Some papers have considered the potential benefits of V2G [20–22], but further analysis will be required once data becomes available. EV batteries can serve as spare energy resources during peak hours, when demand for electric power is greatest, and later draw power back from the grid during off-peak hours. Normally, during peak hours, the power companies must operate additional generators to satisfy demand, and these generators are much more expensive than the primary baseload generators. Utilizing a network of EV batteries plugged into the grid would provide a greener and more efficient alternative to satisfying customers' power needs.

To encourage EV owners to plug in their vehicles and discharge power back to the grid, monetary incentives could be offered based on the amount of power discharged. The net

difference between the incentive for discharging power during peak hours and recharging during off-peak hours would translate directly into a rebate for the EV driver, and over time, this rebate would help to offset the initial investment into the EV itself. V2G would operate in conjunction with the smart grid to ensure that the amount of power discharged during the day does not inconvenience a driver by prohibiting additional travel, and manual thresholds could be established based on the driver's personal preferences.

In order for V2G to be truly effective, the grid must know to what extent it can draw power from an EV. If it drains an EV's battery completely, and the EV is parked at its owner's workplace, then the owner cannot return home and will not likely discharge power to the grid again. However, if the owner needs to commute 5 miles to return home and the grid leaves the battery with 20 miles of charge, both parties benefit. The same considerations hold for charging EV batteries as well. Consider the previous example, except that the battery is completely discharged and the owner plugs it in to recharge. If the owner only needs enough charge for a 5-mile commute, it would not make sense to fully charge the battery, especially during peak hours when the cost of power is greatest. Instead, the grid should only recharge enough for the commute, plus a buffer (e.g., an additional 10 miles of charge).

OTHER OPEN ISSUES

Because EVs have only recently experienced a resurgence in popularity, there are still a number of open issues that have either been insufficiently addressed or completely overlooked; hence, there are plenty of opportunities for academic research to facilitate the transition to EVs and sustainable transportation. Many of these issues, including those introduced in earlier sections, involve topics which fall in the realms of operations research, management science, and analytics. Advances in EV design and battery technologies have led to several automakers announcing plans to

market EV and PHEV models, but a lack of supporting infrastructure and business models threatens to delay the EV transition.

Much of the existing literature on EVs has dealt with great amounts of uncertainty regarding the technological requirements and capabilities of EV infrastructure. The lack of data on driving behavior with respect to EVs further hampers the ability to draw conclusions and ultimately provide valid policy recommendations. As these items become better understood, though, more quantitative models can be formed and more detailed and rigorous analyses can be conducted.

In the following sections, some additional examples of potential research areas are presented that are of particular interest to industrial engineers with a focus on analytics. The goal is not to offer an exhaustive list, but rather to demonstrate the breadth of topics in need of further study and underscore some of the interrelations between the topics.

EV Pricing

One of the foremost issues for EVs is the pricing of the vehicles themselves. The price of an EV will need to be low enough to entice buyers to make the investment and switch over to sustainable transportation. Even if EVs are priced higher than comparable gasoline-powered vehicles, as long as the perceived benefits are substantial (e.g., fuel cost savings, convenience, and image), consumers beyond the current niche group of EV owners will purchase EVs. Incentives and rebates from the government could be given to boost EV sales as well.

Automakers could also offer nonmonetary incentives for early EV adopters. For example, they could provide at-home installation of charging hardware to enable Level II and Level III charging. Another possibility is to offer a program that would allow purchasers to borrow, rent, or share a gasoline-powered vehicle for a limited number of days per calendar year, since driving range will be a concern to new EV buyers. Other creative options could be considered to help tailor EVs to better fit the needs of consumers.

Infrastructure Deployment

In order to support a vast fleet of EVs, a robust charging infrastructure needs to be in place. An obvious question is where to install charging stations, but the solution is less apparent. Depending on the initial deployment priorities, charging stations may be placed in clusters near heavily trafficked areas to maximize convenience, at waypoints along highways to permit long-distance travel, or at a handful of key locations to provide a satisfactory level of service. Their placement, however, will partially be dictated by the existing infrastructure and access to the grid. If the cost of expanding the grid or installing a dedicated circuit is prohibitive, charging stations may need to be installed in less desirable spots to satisfy consumer demand.

Charging stations in densely populated areas will serve the daily commuting needs of most EV drivers, but they will not benefit drivers who must travel longer distances. One of the goals of the EV charging infrastructure will be to extend the limited driving range of EVs, which will require the strategic placement of charging stations in less heavily populated yet still highly traveled areas. Drivers who regularly commute long distances might invest in an EV with a greater battery capacity, but for those who need the extra range infrequently, a second vehicle, likely gasoline-powered, would be necessary if the existing charging infrastructure were insufficient. The additional cost and inconvenience of owning a second vehicle would not suit a majority of EV drivers.

The establishment of the charging infrastructure for EVs will not occur overnight. It will, in fact, take years, even decades, to grow and expand. To best understand how the infrastructure will evolve over time, models will need to be developed. Important considerations will include consumer demand and charging behavior, which will influence the rate of expansion as well as the prioritization of range extension and coverage, and also the coexistence of the EV charging infrastructure with the existing gasoline station infrastructure. Knowing how consumers affect and react to changes in the EV charging infrastructure will facilitate

planning and decision making for charging station locations.

In determining how to build the charging infrastructure for EVs, it will be necessary to determine the source of funding as well. Many of the existing charging stations were funded by the companies that installed them, such as Better Place and Coulomb Technologies, Inc., and those companies collect a fee when the charging stations are used. Other charging stations, paid for by city councils, are free to use. As EVs increase in popularity, the decisions to install charging stations will become more complex as the number of stakeholders increases.

For example, consider a private business that wants to install charging stations in its parking lot. Some of the stakeholders include the business itself, which benefits by providing convenient charging to its patrons; the patrons, who are able to charge their EVs; the charging station manufacturer, which collects a fee each time one of the charging stations is used; and the EV manufacturers (particularly during the earlier phases of EV adoption), whose EVs gain value from the additional infrastructure. The goal is to fairly distribute the cost of the charging stations among the various stakeholders. Such a problem is complicated even further when public funds, which are collected from taxpayers (who may not all own EVs), are used to provide publicly accessible charging stations. Weighing the benefits to individual citizens as compared with society as a whole is both technically and ethically challenging.

Vehicle Telematics

Understanding EV driving patterns will be critical to providing effective charging services. Vehicle telematics provides a means of tracking EV road movements as well as monitoring charging behavior, and communications between the vehicles and the charging infrastructure can direct drivers to the nearest available charging stations. There already exists a software application for mobile devices allowing users to locate nearby charging stations and providing them with more advanced details such as the availability of charging stations and the status of a charging session in progress [23].

As more data becomes available from vehicle telematics systems, researchers will be able to better characterize EV driving patterns and identify opportunities to improve the charging infrastructure. Techniques such as data mining and network analysis will prove useful in uncovering patterns of driving and charging behaviors, which can then be applied to simulation studies to perform experiments and gain even deeper insights into the EV charging networks.

FINAL THOUGHTS

The future of EVs and sustainable transportation is no longer a pipe dream—it is imminent. Automakers have announced plans for mass producing their EV models. Charging station manufacturers have successfully demonstrated their products and installed them for public use. The vehicles and infrastructure are ready to go, but there is still plenty of modeling and planning to do before EVs become a major method of transportation. Together with automakers, charging infrastructure companies, policy makers, and the public at large, researchers in the fields of engineering, operations research, and management science can help to make sustainable transportation a reality.

THE NATURALISTIC DECISION MAKING PERSPECTIVE

CHRISTOPHER NEMETH

GARY KLEIN

Klein Associates Division,
Applied Research Associates,
Fairborn, Ohio

The naturalistic decision making (NDM) approach seeks to understand human cognitive performance by studying how individuals and teams actually make decisions in real-world settings. Three major criteria have appeared in the literature to describe research that counts as NDM study: The research focuses on expertise, it takes place in field settings, and it reflects the conditions (such as uncertainty) that complicate our lives. The most important reason to conduct NDM research is the desire to sympathetically address a question of how individuals or teams and organizations make certain types of decisions in natural settings.

ORIGINS

While researchers had studied behavior in real-world settings, most research through the 1970s was done in the laboratory in order to verify mathematical and statistical models. This normative research approach explored how people *ought* to make decisions. Principles and constraints for decisions were derived from formal or mathematical systems such as deductive logic, Bayesian probability theory, and decision theory. The approach contended that the need to improve decision making arises because human decision makers systematically violate normative constraints [1]. Research in this vein relied substantially on abstractions of human behavior in order to analyze it. For example, the economic theory of Von Neumann and Morgenstern [2] and the expected utility theory of Keeney and Raiffa [3] contended that humans consider available options and choose the one with the highest expected

return. Operations research [4] described normal human performance in well-bounded, concrete domains through methods such as simulation, linear and nonlinear programming, dynamic programming, queueing and other stochastic-process models, Markov decision processes, econometric methods, data envelopment analysis, neural networks, expert systems, decision analysis, and the analytic hierarchy process; see Hillier and Lieberman [5] for more on operations research methods. Nearly all of these techniques involve the construction of reductive mathematical models to describe a system. As early as the 1970s, Shackel [6, p. 436] noted that operations research techniques such as dynamic programming were available “but fail when the problem involves many criteria with changing priorities”

Unfortunately, the training methods and decision support systems that were developed according to principles from these formal systems neither improved decision quality nor were adopted in field settings. People found these tools and methods cumbersome and irrelevant to the work they needed to do [7]. Other research initiatives offered greater potential to understand behavior by studying it in real-world settings. This came to be known as the *naturalistic decision making (NDM)* approach. One of the influences on NDM was Gibson’s [8] ecological psychology demonstrations of how organisms directly perceive their environment, rather than follow abstract experimental constructs. Neisser [9] complemented the Gibsons’ view, encouraging the study of cognition to be more realistic and seek to

- understand purposeful behavior in the real world (outside of the laboratory);
- understand the real-world’s details and the fine-grain structure of available information;
- grasp the kinds of cognitive skills people acquire and develop; and
- examine the fundamental questions of human nature.

Work by deGroot and Simon also formed the foundation for NDM. From 1938 to 1943, deGroot [10], p. 320] collected verbal protocols of chess players while conducting early field studies of how people make decisions. deGroot wanted to determine what separated those who excel at chess from others who do not. He found that the chess master "...sizes up positions more easily and, especially, more accurately." This expert skill appeared to rely on the mental simulation of options and the comparison of reactions to them. Simon [11,12] introduced the notion of *satisficing*, contending that business organizations deal with real-world complexity by using procedures that find "good enough" answers to questions when best answers cannot be obtained. People satisfice by looking for the first workable option, rather than trying to find the best possible option.

By the early 1980s, Kahneman *et al.* [13] showed that individuals rely on heuristics (rules of thumb) to make decisions. Their heuristics and biases (HB) paradigm demonstrated that people did not use strategies in the form of algorithms in order to follow principles of optimal performance. This occurred even when expected utility theory, probability laws, and statistics indicated that an individual was likely to choose certain optimal courses of behavior.

PRACTICE

Researchers need several kinds of skills, knowledge, and attitudes in order to conduct NDM studies. These can be thought of as models, methods, and mind-sets.

Models

The NDM models and theories will help researchers to notice relationships and form expectancies. Without them, these relationships are likely to be invisible. Followed too closely, though, models might also get in the way of taking a fresh look at a phenomenon. For example, the recognition-primed decision (RPD) model [14] describes how people use their experience in the form of a repertoire of patterns that describe a situation's primary causal factors.

Klein *et al.* [15] deliberately chose not to use the RPD model as a framework at the start of studies in sensemaking because it would get in the way of observing the phenomenon. They instead formulated a data/frame model of sensemaking, to examine the interaction between the interpreted signals of events (data) and explanatory structures that account for the data (frames). The data/frame model is compatible with the RPD model but emphasizes different processes and relationships than RPD. Similarly, in a recent investigation of causal reasoning (which is a form of sensemaking), Klein and Hoffman [16] chose to begin with a naturalistic exploration rather than try to extend the data/frame sensemaking model.

Methods

Cognitive task analysis (CTA) [17] is a set of methods such as structured interviews and observations that are used to elicit knowledge gained from real-world experience, analyze it, and use the results to develop representations including descriptions, diagrams, and models. Competence in the use of CTA methods to pursue the question "How, and why, are they doing that?" is more important than knowledge of NDM models. These may be methods to conduct interviews, either about tough cases or about the way a domain is understood; see Crandall *et al.* [17] and Hoffman and Militello [18] for more information. They may be field observation methods or they may be methods to review the existing literature and documentation [19,20]. NDM researchers' use of CTA methods sets them apart from the ecological psychology tradition, which attempts to account for performance in terms on environmental constraints rather than mental activities. NDM researchers typically focus on mental activities such as decision-making and sensemaking strategies, while also trying to be sensitive to the context of a situation.

It is not enough to just read about methods, because methods need to be used to be understood. This is particularly true of methods used to conduct interviews and field observations. The use of NDM methods is a skill, and novices can find it difficult to notice the key indicators or events that seem

so obvious to more experienced researchers. Coaching can improve their practice. Ideally, a more experienced researcher will participate in the same interview or the same observation. Many research methods require practice, such as neuropsychological experiments that depend on inserting implants and developmental studies that depend on gaining rapport with children. Ethnography also depends on skills in observing performance [21,22], and the use of NDM methods similarly requires practice and feedback.

While NDM methods and NDM models are treated separately here, the two are actually linked. The NDM models will determine the kinds of methods researchers use. The application of NDM methods will reflect the kinds of models researchers have in mind about functions such as decision making and sensemaking.

Mind-Sets

A researcher also needs a mind-set, or sensitivity, that is borne of experience. This can make it possible to notice opportunities to learn more about tacit knowledge, or to dig deeper into an application of expertise, or learn about an exercise of decision making or sensemaking or replanning. This type of “tuning” is developed with practice, like any other kind of expertise. HB researchers are impressive in their ability to spot examples of judgment and decision biases. Their long experiences in studying these biases and thinking about them have resulted in a perceptual/conceptual skill. Similarly, the study of expertise can and should lead NDM researchers to become sensitive to subtle cues that others would likely miss.

Professionals gamble on the kinds of skills they will gain as they continue their work. A professional’s mind-sets will make certain things pop out in a situation, and will obscure others. Ericsson and Charness [23] described the importance of deliberate practice and the limited number of skills one could address with deliberate practice. Skill with noticing how people size up situations or detect problems is different than skill with the detection of decision biases. Each kind of skill pays dividends for the conduct of relevant research. The NDM mind-set helps

researchers to conduct effective observations and interviews. It enables them to capture the way people use their experience to handle uncertainty, vague goals, and high stakes, just as the HB mind-set helps HB researchers study consistent errors in judgment.

EVOLUTION OF NDM

Rather than rely on formal models of decision making, the first NDM researchers began by conducting field research to try to discover the strategies that people used. The formal standards approach we just described had looked for ways that people were suboptimal. By contrast, NDM researchers wanted to find out how people were able to make tough decisions under difficult conditions such as limited time, uncertainty, high stakes, vague goals, and unstable conditions. Researchers had already studied these kinds of issues in fields such as medicine [24] and business [25].

The basic research program at the Army Research Institute for the Behavioral and Social Sciences began to fund several NDM researchers during the mid-1980s. The US Navy became interested in naturalistic decisions following the 1988 USS *Vincennes* shoot down incident, in which the crew of a US Navy Aegis cruiser mistook an Iranian commercial airliner for a hostile attacker and destroyed it. Both the Army and the Navy wanted to help people make high-stakes decisions under extreme time pressure and under dynamic and uncertain conditions.

The first NDM conference, in 1989, assembled researchers who studied decision making in field settings. In a chapter that emerged from that meeting, Lipshitz [26] identified no less than nine NDM models that had been developed in parallel. Working separately, multiple researchers all reached similar conclusions. They found that people did not generate and compare option sets, as those who followed the formal standards approach had contended. Instead, people used their experience to rapidly categorize situations, relying on some kind of synthesis of their experience to make these judgments, and the categories suggested appropriate courses of action.

Rasmussen’s [27] model of cognitive control, which distinguished skill-based,

rule-based, and knowledge-based (SRK) behavior, was one of the nine models. SRK explained behavior in terms of a ladder-style diagram that illustrated behavior based on knowledge, rules, or skills and the direct or cut-off paths that an individual might follow depending on experience and effort involved.

Another account, the RPD model [14], describes how people use their experience in the form of a repertoire of patterns. The patterns highlight the most relevant cues, provide expectancies, identify plausible goals, and suggest typical types of reactions in that kind of situation. When people need to make a

decision, they can quickly match the situation to the patterns they have learned. If they find a clear match, they can carry out the most typical course of action. They do not evaluate an option by comparing it to others, but instead imagine—mentally simulate—how it might be carried out. In that way, people can successfully make extremely rapid decisions. The RPD model is a blend of intuition (the pattern matching) and analysis (the mental simulation). The RPD model was based on in-depth interviews with fire-ground commanders about recent and challenging incidents. Those studies found that

Figure 1. Behavioral modeling methods. (Source: Reprinted by permission of Ashgate Publishing [28]).

the percentage of RPD strategies generally ranged from 80% to 90%.

Figure 1 portrays Jens Rasmussen's [[28], p. 75] view of how methods to model behavior have evolved (from outer to inner circles) from normative models of rational behavior, to models in terms of deviation from rational behavior, to representations of actual behavior. The figure depicts NDM in this latter stage along with Rasmussen's SRK model, Weick's and Senge's concepts of learning organizations, and Bucciarelli, Rasmussen and Vicente's concept of creativity-constraint trade-off. Developed in the same time period, diagnostic and decision-making studies arrived at similar conclusions. For example, studies of process plant operation error reports led to the development of the SRK model as a replacement for decision-making models, and the skills and rules portion of the SRK model are similar to recognition-primed NDM model that evolved from field studies of fireground commanders.

CHALLENGES FOR NDM

Like any research approach, NDM has adherents and critics. The judgment and decision making (JDM) researchers from the formal standards tradition had largely ignored experts, or had devised paradigms to show the flaws in expert judgments. The lead article by Lipshitz *et al.* [29] on "NDM in behavioral decision making" elicited 16 commentaries by JDM researchers, many of them critical. For example, Klayman [30] questioned whether NDM's reliance on experts can produce results that can be generalized beyond the particular nature of their own experience. Tieggen [31] probed whether distinctions can be clarified between prescriptive and descriptive approaches, and between a research program and its results. Bazerman [32] queried whether the standard of expert decision making is suitable to provide a benchmark for real-world decisions by those who are not experts.

A few critical themes related to NDM have evolved since its start. The following are some of the main concerns people have with the field.

NDM Research and Science

Some people ask whether NDM research counts as science. While few NDM projects try to test hypotheses or generate falsifiable claims, they still follow a scientific approach. The scientific method begins with observation/examination of the phenomenon, followed by theory generation, and then theory testing. NDM research primarily takes place at the initial stage, with observation and examination. The basic NDM question "How/why do they do that?" is a way to gain new knowledge and formulate, or at least seed, new theories. The NDM community addresses an earlier stage of the scientific method than the JDM/HB communities. Suggestions that NDM studies institute control groups, randomize treatment effects, counterbalance conditions, and explicitly test hypotheses in order to become "more scientific" miss the added value that a front-end investigation of cognitive processes in natural settings provides.

Very few NDM studies set out to test a hypothesis, so the studies do not look like science to experimental psychologists who are used to conducting controlled experiments that manipulate variables in order to evaluate theories and describe lawful relationships. However, many NDM studies collect and analyze data. For example, Lipshitz and Strauss [33] investigated how military officers manage uncertainty. Klein *et al.* [34] studied how firefighters make decisions under time pressure and uncertainty. Both of these studies collected and analyzed data that could be used by other researchers who sought to replicate the findings. The article by Lipshitz and Strauss [33] is also widely cited in different research communities and several empirical replications of the firefighter study have been conducted.

Falsifiability is the second, related criterion for scientific research. The RPD model satisfied this criterion. Klein *et al.* [35] tested the hypothesis that the first option people considered was of reasonable quality, rather than being random. The results supported the RPD model, and Johnson and Raab [36] later replicated those results. Falsifiability encourages controversy that calls for more data collection. McLennan

et al. [37] criticized some of the limitations of the RPD model and demonstrated the importance of prepriming. Cohen *et al.* [38] similarly modified the RPD model in a recognition/metacognition model. Lipshitz and Ben Shaul [39] have criticized the data/frame model of sensemaking [15] because of vagueness regarding the concept of a frame.

Relationship between NDM and JDM/HB Traditions

The earlier discussion of mind-set noted that HB researchers have tuned themselves to notice things that NDM researchers miss, and ask tough questions about the skill level of subject-matter experts used in NDM research; see Shanteau [40], for an NDM approach to expertise assessment. Efforts are underway within JDM and HB schools to press beyond simple conclusions and to search for the cognitive basis for decision biases [41]. In the pursuit of these questions, JDM/HB researchers are making important findings about the strategies people use. If we can get past our aversion to the term “bias,” the NDM community can learn a great deal from these efforts. And if the JDM/HB community can get past its aversion to the term “expertise” we might be able to forge a productive dialog.

We can also improve NDM practice by making use of recent developments in behavioral economics, which [42] have summarized well. The behavioral engineering they describe seems entirely consistent with the NDM interest in finding natural ways to support and improve decision making.

The NDM community may also be able to use its experience in field settings and its background in human factors to suggest ways to improve JDM applications. We have all seen our share of failed systems and methods, and we have developed cognitive systems engineering and resilience engineering methods to overcome many problems. Bordley [43] suggested that these experiences and methods could be useful for JDM researchers who seek to develop applications. NDM methods of cognitive task analysis may also be useful for JDM researchers who look for insights into the strategies used by target audiences

[44]. Cooksey [45] identified several ways that NDM could partner with JDM to form an integrated decision science: emphasize the decision context, understand constraints on (as well as capabilities of) decision makers, avoid oversimplification, examine individual and organizational learning, and contrast focus of process and outcome.

The Treatment of Error

NDM has been greatly interested in error from its inception. One of the initiating events for NDM was the shoot down of an Iranian airliner by the USS Vincennes. The event contributed to a lengthy research program on decision making for Aegis cruiser command staff, “Tactical Decision Making Under Stress” (TADMUS). Misperceptions and erroneous acts that led to the incident at the Three Mile Island nuclear power facility helped to guide the cognitive systems engineering movement [46].

Reason [47] has distinguished between sharp end errors (the people in an organization who make poor judgments or make poor choices of actions) and blunt end errors (the organizational dynamics, such as inadequate training or conflicting priorities) that contributed to the sharp end errors. The JDM/HB communities have focused on the former. They have identified systematic errors that are independent of organizational pressures. These are the judgment and decision biases.

The NDM community needs to reexamine the HB literature because systematic errors clearly play a role in natural settings, and fields such as behavioral economics have been successful in generating meaningful interventions. At the same time, the JDM and HB communities can benefit from the NDM research on errors, particularly our examination of the dynamics of a situation that can increase the likelihood of errors [48]. Snook’s book on friendly fire is a good example of poor decisions that stemmed from organizational dynamics rather than from biases.

CONTINUING WORK

From the very start of the NDM community in 1989, researchers studied more than

just judgment and decision making. Theoretical constructs such as the RPD model [34] depended heavily on situation awareness, sensemaking, story construction, and mental simulation. Klein *et al.* [49] described this expansion as *macrocognition*. Continuing work in NDM seeks a better understanding of each of these areas, how they are related, and how they occur at the individual and team level.

Macro cognition has been described by others as follows: situated cognition and extended cognition [50]; the cognitive adaptation to complexity [51]; and the cognitive functions that are performed by actual practitioners in natural decision-making settings that are generally performed by a team working together in a natural situation, and usually in conjunction with computational artifacts [52]. The primary reason for describing macrocognitive functions is that many researchers have received their initial training in laboratory settings. They are not used to considering functions such as problem detection that are not easily studied under controlled conditions. The desire to control the experimental conditions is common in cognitive research. By contrast, the NDM orientation is to be inclusive and curious about different aspects of cognition that will affect the way people handle the conditions such as limited time, uncertainty, high stakes, vague goals, and instability [53]. The term *macrocognition* is intended to change the mind-set of the researcher. Instead of feeling discomfort regarding these types of complexities we want NDM researchers to feel excitement and curiosity about how people adapt to them.

The primary macrocognitive functions are decision making, sensemaking, planning/replanning, problem detection, learning/adaptation, and coordination. In most settings, these functions are related to each other. Decision making usually depends on sensemaking. Planning/replanning depends on problem detection and sensemaking and decision making. Replanning depends on the diagnosis of difficulties, which is a form of learning that relies on sensemaking. Coordination of resources and people depends on problem detection, sensemaking and

replanning, and leads to decision making. Because of this an NDM investigation will rarely be confined to only a single function. The research may highlight one or another of the functions, but the researchers will benefit from knowledge about the other functions and processes. That is the reason NDM researchers have been able to go back to the studies of a macrocognitive function such as decision making and use the incident accounts in studies of other functions such as sensemaking and problem detection.

THE NORTH AMERICAN OPERATIONS RESEARCH SOCIETIES

KARLA HOFFMAN
George Mason University,
Systems Engineering
and Operations
Research Department,
Fairfax, Virginia

Each of the operations research societies that exist in North America has similar goals. The purpose of these is to promote the advancement of knowledge, interest, and education in operations research by providing mechanisms for the exchange of information through the organization of conferences, the promotion of advances in the field, and the production of books, journals, magazines, videos, web materials, and other media that describe the developments, technologies, and successes of the field. Multiple prizes are awarded by each society honoring such achievements.

Each of the societies is also part of a larger worldwide umbrella organization known as the *International Federation of Operations Research* (IFORS; <http://www.ifors.org>). IFORS is divided into regions, and the two societies that are officially part of the North American (NORAM) group are The Canadian Operations Research Society (CORS) and the Institute for Operations Research and the Management Sciences (INFORMS). The Mexican Institute of Systems and Operations Research/Sociedad Mexicana de Investigacion de Operaciones (IMSIO/SMIO) does not belong to this regional group but rather to the Association of Latin-Iberoamerican Operations Research Societies (ALIO), which includes societies representing Bolivia, Chile, Columbia, Cuba, Ecuador, Mexico, Peru, and Venezuela as well as the Spanish Society of Statistics and Operations Research.

CORS (<http://www.cors.org>) was established in 1957 (the same year during which

IFORS was created) and held its inaugural meeting in 1958. CORS serves its members through a variety of publications and services including its quarterly *Bulletin* (started in 1962); its journal, *Information Systems and Operations Research* (INFOR), which is published jointly with the Information Processing Society of Canada, published quarterly; a traveling speaker program; an annual Graduate Student Conference; and grants to attend teaching effectiveness workshops. In addition, CORS honors its members with a variety of awards including the Harold Larnder Prize for international distinction in operations research; the CORS Award of Merit; the CORS Service Awards; and the CORS Practice Prize. CORS holds an annual conference that is often held jointly with “sister organizations” such as the Information Processing Society of Canada. CORS includes a variety of sections including Atlantic, Québec, Kingston, Toronto Student, Southwest Ontario, Waterloo Student, Winnipeg, Saskatoon, Calgary, Edmonton, Vancouver, and Vancouver Student.

INFORMS (<http://www.informs.org>) is the largest operations research society in the world. INFORMS holds two major conferences per year as well as a variety of smaller meetings that are organized by its many special-interest groups, societies, and fora. The fall meeting, known as the *National meeting*, is primarily a forum for operations research academics and has the largest attendance of any operations research meeting worldwide. The other meeting, labeled the Analytics Conference, is directed toward practitioners. The Analytics Conference includes tutorials and workshops related to the use of advanced analytics within business and government; workshops for operations research analysts on soft skills that enhance one’s ability to communicate ideas and results to management; and presentations by major industry figures on operations research successes as well as an executive forum. In addition to these meetings, INFORMS often plans a summer

International meeting which is usually organized jointly with another operations research society.

INFORMS is composed of two former organizations: The Operations Research Society of America (ORSA), which was found in 1952, and the Institute of Management Science (TIMS) found in 1953. Both these organizations had similar objectives, although ORSA was often perceived to be more engineering and academically oriented with a strong military focus, whereas TIMS was considered to be more business and applications focused with a stronger international perspective. From the time of their establishment, these societies often held joint conferences, had many officers in common, and produced joint publications. In 1974, the organizations held their first joint National meeting and continued to do so until the merging of the organizations in 1995. The discussion of merging the two organizations took place as early as 1957 [1] and in 1975, a "Blue Ribbon Committee" was formed to identify how the two societies could cooperate more effectively [2]. For a historical description of the merging of these two societies and how it was finally accomplished, refer to the article by Keller and Kirkwood [3]. For a more complete description of the activities of the professional societies, refer to the articles by Assad and Gass [4] and Salveson [5].

INFORMS publishes multiple journals (*Decision Analysis*, *Information Systems Research*, *INFORMS Journal on Computing*, *Interfaces*, *Management Science*, *Manufacturing and Service Operations Management*, *Marketing Science*, *Mathematics of Operations Research*, *Operations Research*, *Organizational Science*, *Service Science*, *Transportation Science*, and *INFORMS Transactions on Education*) as well as a tutorial and book series. It publishes three magazines: *OR/MS Today*, *Analytics*, and *OR/MS Tomorrow*. Other programs include a speakers program, a high-school teachers' program, a History and Traditions Committee that encourages and facilitates the collection and preservation of materials relating to the history and traditions of OR/MS, a doctoral colloquium, a teaching

effectiveness colloquium, and young practitioners' workshop. INFORMS is divided into communities; as of 2012, there are 10 societies (*Applied Probability*, *Computing*, *Decision Analysis*, *Health Applications Society*, *Information Systems*, *Manufacturing & Service Operations Management*, *Marketing Science*, *Military Applications Society*, *Optimization*, *Simulation*, and *Transportation Science & Logistics*), 22 subdivisions, 5 fora (interest groups that are neither discipline nor geographical), and 31 regional groups. These entities hold their own meetings as well as contribute substantially to the content of the national meeting.

The institute recognizes the achievements of its members through a variety of prizes, including the John von Neumann Theory Prize; the INFORMS President's award; the INFORMS Fellows awards; the George E. Kimball Award for distinguished service; the INFORMS Prize for the Teaching of OR/MS Practice; and the INFORMS Impact Award. Many other prizes are awarded through the subdivisions.

Almost from the beginning, CORS and INFORMS have regularly held joint meetings, and have provided each other's members with reduced prices for membership and journal subscriptions. More recently, these two societies have worked with ALIO to organize joint meetings that encourage collaboration and dissemination among the Americans.

There are a number of "sister" organizations with research interests that are closely aligned with those of INFORMS and CORS. The most closely aligned is the Institute of Industrial Engineers (IIE), which is the world's largest professional society dedicated solely to the support of the industrial engineering profession and individuals involved with improving quality and productivity. Founded in 1948, IIE is an international, nonprofit association that provides leadership for the application, education, training, research, and development of industrial engineering. For more on this organization, visit <http://www.iienet.org>. There are many other organizations that also represent individuals whose research technologies are closely related to those of operations

research analysts. We end this short note with a listing of those organizations and their web sites:

- Academy of Marketing Science (<http://www.ams-web.org/>);
- AGIFORS (Airline Group of the International Federation of Operational Research Societies; <http://www.agifors.org/>);
- Academy of Management's Operations Management Division (<http://om.aomonline.org/>);
- ASQ (American Society for Quality; <http://www.asq.org/>);
- DSI (Decision Sciences Institute; <http://www.euro-online.org/>);
- HIMSS (Healthcare Information Management and Systems Society; <http://himss.org/>);
- IFIP (International Federation for Information Processing; <http://www.ifip.or.at/>);
- LMI (Logistics Management Institute; <http://www.lmi.org/>);
- MORS (Military Operations Research Society; <http://www.mors.org/>);
- The Mathematical Programming Society (<http://www.mathopt.org/>);
- PMSA (Pharmaceutical Management Science Association; <http://www.pmsa.net/>);
- POMS (Production and Operations Management Society; <http://www.poms.org/>);
- SCS (Society for Computer Simulation International; <http://www.scs.org/>);

- SDP (The Society of Decision Professionals; <http://www.decisionprofessionals.com/>);
- SIAM (Society for Industrial and Applied Mathematics; <http://www.siam.org/>);
- SIM (Society for Information Management; <http://www.simnet.org/>);
- SJDM (Society for Judgment and Decision Making; <http://www.sjdm.org/>);
- SOLE (Society of Logistics Engineers; <http://www.sole.org/>);
- TRB (Transportation Research Board; <http://www.nas.edu/trb/>);
- WSC (Winter Simulation Conference; <http://www.wintersim.org/>).

THE OPERATIONAL RESEARCH SOCIETY OF SINGAPORE

LAI KAH WAH
Operational Research Society of
Singapore, Kent Ridge,
Singapore

HISTORY OF ORSS

How was the Operational Research Society of Singapore (ORSS) founded? At a June 1974 seminar on “Application of OR” held at the (then) Nanyang University, the participants strongly felt that an association should be formed to promote OR in Singapore [1]. In December 1974, a *protem* committee was formed. By February 1975, the society name had been decided upon and the constitution was drafted. ORSS was officially registered on November 21, 1975. The inaugural Annual General Meeting (AGM) was held on March 26, 1976.

ORSS was admitted as a full member of the International Federation of Operations Research Societies (IFORS) in May 1978. ORSS is a founding member society of the Asia-Pacific Operations Research Societies (APORS) in August 1984; APORS was formally launched in March 1985. The founding president of ORSS, Prof Chew Kim-Lin, was APORS president for 1998–2000.

From its beginning with a handful of members, ORSS grew to more than a hundred members in the late 1980s, despite a deliberate decision to keep it as narrow-based as possible. The growth can be attributed to the establishment of OR [or operations analysis (OA) in military parlance] as a technical discipline in the Singapore defense community [2]. The sustained use of OR-related techniques, especially discrete-event simulation and mathematical programming, by other large home-grown organizations namely the Port of Singapore Authority (now PSA Corporation), Singapore Airlines,

and the Land Transport Authority likewise encouraged their in-house practitioners to join ORSS.

Since then, membership has been maintained at hundred-plus persons, though the proportion—and number—of life members have grown steadily each year. Along with the retirement of all the pioneer members, ORSS has seen regular, albeit small, annual enrollments of young analysts with interest in exploring OR as a career skill-set.

ACCOMPLISHMENTS

For the first decade of its existence, ORSS organized several small-scale seminars with academic focus.

Talks on actual applications in industry were gradually added, from the 1990s onwards. These talks and the academic seminars, still going on regularly, are aimed at raising current awareness of issues, techniques, and tools.

In June 1995, ORSS cohosted with the National University of Singapore (NUS), the first-ever INFORMS International Conference. This event was assessed as an unqualified success, attracting a few hundred participants from all over the world.

In July 2000, ORSS cohosted the Fifth Triennial APORS Conference. This was held over three days with more than 200 attendees from the Asia-Pacific region.

To encourage students' interest at both undergraduate and postgraduate levels, ORSS sponsors prize awards annually to the top graduating students in the NUS B Eng Industrial and Systems Engineering (ISE) and M Sc (ISE) courses who had specialized in the OR tracks.

Occasional industrial visits to organizations applying OR are also organized. Such visits serve to highlight practical aspects of ground OR to younger and student members.

ORSS has just initiated discussions with an advisory director of the US Military Operations Research Society (MORS). Given

the sizable number of ORSS members working on defense and national security, there is much interest in exploring technical dialogues and joint events with MORS.

PUBLICATIONS

The ORSS newsletter was started in 1977, averaging two to three issues per year. In the pre-Internet years, that is the 1970s–1980s, hardcopies of the newsletters were printed and distributed to both, individual members and organizations. Beginning in the early 2000s, dissemination of newsletters was switched to soft-copies. Recognizing the need for quick, timely, bite-sized information since then, ORSS now keeps its members updated via emailing lists. For members' convenience, larger files are uploaded to the ORSS' website. Some more technology-savvy members are suggesting Facebook and Twitter as alternative Internet-based channels.

ORSS first published the Asia-Pacific Journal of Operational Research (APJOR) in 1984. APJOR was subsequently adopted as APORS' main technical journal. APJOR provides a forum for practitioners, academics, and researchers in OR and related fields, within and beyond the Asia-Pacific region [3].

As for milestone publications, two special compilations of largely practice-oriented articles were published to commemorate the 10th and 20th anniversaries of ORSS.

REGULAR MEETINGS

As called for in its constitution, ORSS management committee (MC) meetings are held quarterly. Members of the MC are elected, or reelected, at each AGM, usually held in April of each year. For diversity, each MC usually comprises a balanced mix of members from different organizations and sectors. Representatives from the MC are also nominated to attend APORS and IFORS Council meetings.

OFFICE HOLDERS

So far, ORSS has had 11 presidents, from academia, government, and industry. Their

names and their terms of office are as tabulated:

S/N	Name ^a	Term of Office
1	<i>Chew</i> Kim-Lin	1976–1978, 1982, 1984–1985, 1987, 1989–1990
2	William <i>Liu</i> Wei Hai	1979–1981
3	<i>Kwok</i> Kah Chee	1983
4	<i>Yeong</i> Wee Yong	1986
5	<i>Tan</i> Thiam Soon	1988
6	<i>Liu</i> Kwai Wah	1991–1995
7	<i>Sim</i> Cheng Hwee	1996–1997
8	<i>Yu</i> Wei Shin	1998
9	<i>Poh</i> Kim Leng	1999–2001
10	<i>Tan</i> Kok Choon	2002–2005
11	<i>Lai</i> Kah Wah	2006–current

^aFamily name italicized.

The other members of the current (2009) 34th MC are: *Tan* Kok Choon (Vice President), *Ng* Kien Ming (Honorary Secretary), *Patrick Hoe* Puay Hian (Honorary Treasurer), *Ryan Chang* Khang Yang (Assistant Honorary Secretary), *Tiah* Yao Ming, *Andrew Tan* Chee Seng, *Alvin Ong* Siau Wah, and *Toh* Kaiyang (Committee Members). The two honorary auditors are *Ng Ee Chong* and *Pim Beers*.

THE OPERATIONAL RESEARCH SOCIETY

GRAHAM SHARP
The OR Society, Birmingham, UK

HISTORY

In April 1948, the Operational Research Club was established in London as the first OR association in the world. Five years later the OR Club became The OR Society.

The term *Operational Research* was first used in 1938, as a descriptive term for the use of scientists to assess, at first hand, military situations and the deployment of devices therein. An example of this was the use of scientists in the process of evaluation of radar as an aid to air defence up to and including the War years.

During the Second World War, OR sections were set up in various branches of the British armed forces. These were followed by the establishment of similar sections in the services of the United States and Europe. After gaining distinction throughout the War years, the advocates of OR sought to secure its future in peacetime. There followed a period from 1945 until the mid-seventies when use of OR methodologies expanded rapidly into nationalised industries, the civil government, and the corporate sector.

Although OR may have been born in 1938, it was to be another 10 years before it developed a professional body. This came about when, in the autumn of 1947, a group of distinguished gentlemen met for an informal dinner at the Athenaeum Club in London. At this dinner, a momentous decision was made to form an OR Club. Those at the dinner included luminaries such as Sir Charles Goodeve, Professor P.M.S. Blackett (later Lord Blackett), Dr C. Gordon, and Sir Charles Tizard. The OR Club, the world's first body set up to cater for the OR profession, was inaugurated in April 1948 with an initial membership of 50.

In a communication received by the OR Society dated 16th August 1976, Sir Charles Goodeve explained the delay between founding the OR Club and inaugurating The OR Society: "We had to call it a club first of all to get over certain legal difficulties with regard to membership. We thought these difficulties would be solved in a couple of years, but in the event it took five or six years. However, the time was not wasted because we got the Quarterly going and our constitution finally settled." The Quarterly to which Goodeve referred was the *Operational Research Quarterly (ORQ)*, the world's first OR journal, which later became the *Journal of the Operational Research Society (JORS)*.

Volume 1, No. 1 of the *ORQ* was duly published in March 1950—the first editors were Max Davies and Roger T. Eddison. In the editorial notes of that first issue, the reasoning behind the Quarterly is clearly set out. "The main purpose of the *ORQ* is to assemble in one place as much as possible of the information that OR workers now find (or fail to find) scattered widely over the very large body of the scientific and technical literature. The method is to provide a quarterly collection of abstracts of relevant papers and articles, taken from as wide a field as possible." The first article to appear in the *ORQ* was "Operational Research" by Professor P.M.S. Blackett. The Quarterly continued as such until 1978, after which time it was renamed the *JORS* with 12 issues a year.

By 1955, interest in OR had spread to most western countries. Membership levels grew steadily, the original 50 had increased to a total of around 1250 members in 1964. Membership of the Society reached a plateau at around 3000 in the early 1970s and has remained at roughly the same level ever since.

THE OPERATIONAL RESEARCH SOCIETY TODAY

The OR Society continues to be an innovator and leader in its field. Today, The Society has

around 3000 members in 53 countries who receive a wide range of services and benefits. The Society's training programme is the most comprehensive OR training programme on offer anywhere in the world. Its annual conference is the largest national conference outside the United States, and its series of YoungOR conferences, inaugurated in 1980, is the world's leading conference for young OR workers.

Inside OR is the world's leading monthly OR magazine, carrying news, features on OR methods, personalities and events, debate, and a comprehensive notice board section providing information on what's happening in the OR world.

As a means of raising the profile of OR, The OR Society set itself an ambitious "stretch goal" that every school child should have heard of OR. The OR in Schools initiative has been the driver for the development of a website containing materials that can be used by mathematics teachers, young people, and careers advisers. The Society has also produced a DVD, downloadable from the website www.LearnAboutOR.co.uk that explains what OR is and how it helps people to make better decisions. The DVD won the British Institute of Videography Award for the Best Corporate Video 2009.

In addition to its own website www.theorsociety.com, The OR Society has two other websites—www.scienceofbetter.co.uk—developed in association with the Institute for Operations Research and the Management Sciences (INFORMS) as a mechanism to communicate the benefits of OR to the business community and www.LearnAboutOR.co.uk which was designed in response to the OR Society's OR in Schools initiative.

NOTEWORTHY ACCOMPLISHMENTS

- The world's first OR Society
- The world's first OR Journal
- Comprehensive training programme
- Largest national conference outside the United States
- Young OR conference

- Launched two specific Journals for Knowledge Management and Simulation
- Website designed in response to the OR Society's OR in Schools initiative—www.LearnAboutOR.co.uk
- Award-winning DVD about OR

PUBLICATIONS

- *Inside OR* is the magazine circulated to all members of The OR Society. The magazine is distributed both in print and electronically every month. *Inside O.R.* contains news about current events in OR, forthcoming meetings, conferences and training courses, awards and prizes that are available, and articles of interest to the OR community.
- *OR Insight* is an interesting and stimulating publication that appeals not only to OR practitioners and consultants, but also to managers and others wishing to learn more about OR in practice. The journal seeks to provide information about not just the scope and potential of OR but also about developments in related areas. Contributions are particularly sought from OR practitioners, consultants, and others with experience in OR.
- *The Journal of the Operational Research Society (JORS)* is published 12 times a year by Palgrave Macmillan on behalf of The OR Society. JORS is the world's longest established OR Journal and aims to present papers that are relevant to practitioners, researchers, teachers, students, and consumers of OR and which cover the theory, practice, history, or methodology of OR
- *Knowledge Management Research & Practice (KMRP)* is published quarterly by Palgrave Macmillan on behalf of The OR Society. KMRP provides an outlet for high quality, peer-reviewed articles on all aspects of managing knowledge, organisational learning, intellectual

capital, and knowledge economics. This includes not just those focused on the organisational level, but all levels from that of the individual to that of the nation or profession and includes both theoretical and practical aspects, and especially the relationship between the two. There is a particular emphasis on cross-disciplinary approaches and on the mixing of “hard” (e.g., technological) and “soft” (e.g., cultural or motivational) issues. Rigorous contributions from both academics and practitioners are welcomed.

- *The Journal of Simulation (JOS)* is published four times a year by Palgrave Macmillan on behalf of The OR Society. The journal publishes both articles and technical notes from researchers and practitioners active in the field of simulation. Within *JOS*, the scope of the field of simulation is taken to include the techniques, tools, methods and technologies of the application, and the use of discrete-event simulation in a wide range of domains including, for example, manufacturing, service, defence, health care and commerce.

MEETINGS

Special Interest Groups

A Special Interest Group of The OR Society is intended to serve some or all of the following objectives:

- to provide a focal point where members with a common interest in a particular OR area can meet together and exchange ideas and experience;
- to further technical development in a particular sphere;
- to promote a particular aspect of OR and to increase management understanding of the same;
- to help represent the OR Society viewpoint in joint activities with other Societies;
- to prepare written material on the “state of the art” for general publication;
- to provide education for new entrants to the profession or to the area covered by the Special Interest Group.

Groups are arranged for the following areas of special interest: Agriculture and Natural Resources, Community OR Network, Complex Systems Discussion Group, Criminal Justice, Decision Analysis, Defence, Financial Services, Forecasting, Health & Social Services, Independent Consultants’ Network, Information Systems, Local Search, Mathematical Programming, OR and Strategy, OR for Developing Countries, Problem Structuring Methods, Productivity Measurement, Simulation, and SD+.

PAST PRESIDENTS

Sir Owen Wansbrough-Jones	1954–1955
Sir William K Slater	1956–1957
Professor M G Kendall	1958–1959
The Earl of Halsbury	1960–1961
Professor B H P Rivett	1962–1963
Professor G A Barnard	1964–1965
Professor R T Eddison	1966–1967
Mr E C Williams	1968–1969
Mr S Beer	1970–1971
Professor K D Tocher	1972–1973
Mr R C Tomlinson	1974–1975
Mr A M Lee	1976–1977
Professor M G Simpson	1978–1979
Mr G H Mitchell	1980–1981
Professor K B Haley	1982–1983
Dr R S Stainton	1984–1985
Professor JV Rosenhead	1986–1987
Professor JV Rosenhead	1986–1987
Dr J C Ranyard	1988–1989
Mr P N Thornton	1990–1991
Professor C B Chapman	1992–1993
Professor L C Thomas	1994–1995
Mr I J Disley	1996–1997

4 THE OPERATIONAL RESEARCH SOCIETY

Professor R G Dyson	1998–1999
Professor M Pidd	2000–2001
Mr J Gibb	2002–2003
Professor V Belton	2004–2005
Professor J D Griffiths	2006–2007
Mrs S M Merchant	2008–2009
Professor R Eglese	2010–2011

THE OPERATIONS RESEARCH SOCIETY OF SOUTH AFRICA

HANS W. ITTMANN
CSIR Built Environment, Pretoria,
South Africa

V. S. SARMA YADAVALLI
Department of Industrial and Systems
Engineering, University of Pretoria,
Pretoria, South Africa

HISTORY OF ORSSA

The Operations Research Society of South Africa (ORSSA) was formally founded on Thursday 20 November 1969 in Johannesburg [1]. Some 150 individuals, from all over South Africa and also the then Rhodesia, were present at this founding meeting. The society is one of only a few OR societies currently active on the African continent, in fact, for many years it was the only one on the continent. It is interesting to note that the involvement of South Africans in OR goes back to World War II. South African scientists were members of the “Blackett’s Circus”, for example, Professors Solly Zuckerman and Frank Nabarro [1]. In addition Dr Basil Schonland, professor in geophysics at the University of the Witwatersrand, who was initially responsible for the South African efforts around the development and application of radar, later became the superintendent of the British Army Operational Research Group [2].

The use and practice of OR in South Africa has its roots in the mining industry [3] and in this regard, the Operational Research Bureau was founded by Herbert Sichel in 1952, mainly to act as consultants to the mining industry [4]. Various other large organizations embraced OR in the 1950s and 1960s in South Africa including the Defense Force, the main rail operator, and also the Council for Scientific and Industrial Research (CSIR), the largest public research establishment in the country. A South African,

RR Tusenius, attended the first OR conference held in Oxford in September 1957 [5]. With this growing interest in OR it was inevitable that this would lead to the establishment of a formal society, which happened in 1969. One of the biggest supporters and long-standing friends of the new society was Professor Patrick Rivett, a well-known, international OR personality from the University of Sussex in the United Kingdom. Rivett was present at the inaugural meeting in 1969 [1].

As indicated above, the mining industry was a fertile ground for OR applications in the early years of OR in South Africa. Whereas mining companies had strong OR groups, these all disappeared during the late 1970s and early 1980s when mining companies came under severe financial pressures. The development of OR was given a boost in South Africa when the CSIR established an OR group in the early 1960s. Many of the members of this initial group went to different universities where they were instrumental in establishing the first formal academic programs in South Africa [6]. The group at the CSIR continues to be one of the strongest OR groups in the country. Over the years, their work has involved more of consultations. OR also spread to industry, commerce, and defense. It is difficult to pinpoint a very strong sector where OR was used or is being used because of the wide variety of areas of application. A group in one of the banks was dominant at one stage; energy modeling was conducted during the 1970s and early 1980s by the CSIR together with the University of Pretoria; it is a well-known fact that in the mid-1970s a very strong group was established to conduct defense OR although little was known about what exactly the group was doing. Today there are still defense OR groups, possibly smaller than before democratization. Another noticeable area of application and a feature for which South Africa is famous, is wildlife management, including the conservation of the wildlife heritage and ecological and game range management. Considerable and

meaningful work was conducted in these areas [3,7,8]. Over the past 10 years a very strong modeling and simulation group has been developing at SASOL, the largest chemical company in South Africa, which is well known for the production of gasoline from coal. Today, this group is possibly the only such group in industry and by far the largest. A disappointing feature of OR in South Africa is the lack of OR usage in the public sector. The reasons are many but there is a general lack of appreciation of the value and potential contribution of quantitative methods and scientific problem solving.

In the academic environment, the University of South Africa (UNISA) was the first to establish a department that focused on traditional OR. This happened in the early 1970s and was by far the strongest OR university department for many years. The department has remained strong but the focus has shifted more toward financial modeling. One can find noticeable teaching in OR at various universities, namely, Stellenbosch University, the University of Cape Town (UCT), the University of the Witwatersrand (WITS), the North-West University, and also the University of Pretoria. One or two of the “previously disadvantaged institutions”, or Historically Black Universities, have relative large OR departments. In all cases except one, the departments that currently teach OR have different names such as decision sciences, statistical sciences or industrial engineering. At Stellenbosch University OR is located in the Department of Logistics. The teaching of OR at all these universities has always been dependent on the availability of suitable lecturing staff.

ORSSA exists primarily to further the interests of those engaged in, or interested in, OR activities. To achieve these objectives, it is involved in matters that concern OR practitioners in general, such as drawing up guidelines for OR education, presenting short courses and marketing OR, and providing information to the public on the nature of and career opportunities in OR. Ever since its inception, the society has had a variety of activities, initially mainly through three chapters and an annual conference, but these have been extended over the years.

Past and current activities of the society are the following:

- An annual conference is held in different parts of the country every year, usually in September of a year. The conference stretches typically over two or three days with around 70 to 80 delegates nowadays. In addition, the society endeavors to invite an international OR expert as the keynote speaker. In 1996, the annual conference was held in a neighboring country, namely, Swaziland. Joint conferences have also been held in the past with the Statistical Association of South Africa as well as the Institute for Industrial Engineers. In 2007 ORSSA also hosted the Operations Research Practise in Africa (ORPA) conference in Cape Town jointly with its national conference.
- The main mechanism of communicating with members is through a newsletter, which is published quarterly in printed format. The appearance of the newsletter has changed over the years and it is now a very professional looking newsletter.
- The society initially established three chapters and over the years, these have been extended to cover the entire country. Currently there is local representation in the form of five local chapters located in Cape Town, Johannesburg, Pretoria and two regions, namely, KwaZulu-Natal and the Vaal Triangle. All these chapters are active in one way or another.
- One of the founding members of the society, Tom Rozwadowski, died tragically with his family in 1971. In his honor, the society established the Tom Rozwadowski award, which is awarded annually for the best paper published by a member of the society.
- The society also runs a student competition annually where the best Honors and MSc students in the past year are recognized by the society in the form of a monetary prize and a certificate.
- In 1981 the first international meeting held in South Africa was a joint

- Israeli–South African conference on OR. It was held at the CSIR Conference Center in Pretoria and attracted nearly 200 delegates.
- The second international conference on “Operations Research in Resources and Requirements in Southern Africa” was held in 1984, also at the CSIR in Pretoria. This was an IFORS-sponsored event that included nine prominent international speakers.
 - In 1985 ORSSA established its own bi-annually published journal, ORiON. The journal has developed over the years to a quality publication with a high standard and an international advisory board. Volume 25 Number 1 has just been published.
 - A very successful Multi-Criteria Decision Making (MCDM) conference was held in January 1997 in Cape Town. Some 170 people, mainly international delegates, attended the conference.
 - The fourth International Conference on OR for Development (ICORD) was organized by ORSSA in May 2001 in the Kruger National Park. People from 14 countries attended. Although it was a very small conference it was nevertheless, a very successful event.
 - ORSSA initiated a project “OR into Africa” that endeavors to establish a community of OR workers in the development arena within South Africa.
 - In addition, ORSSA was also involved in assisting the East African OR fraternity to organize its first OR conference and to establish its own society.
 - Arguably the highlight of ORSSA’s existence was when the society’s bid to host the 18th triennial conference of the International Federation of Operations Research Societies (IFORS) was accepted by IFORS. This conference was held in July 2008 at the International Convention Center in Sandton and was, by all accounts, a very successful conference.
 - ORSSA has its own website at the following address: www.orssa.org.za.
 - The society is managed by an Executive Committee that *inter alia* consists of a President, who serves for two years, a Vice President, Secretary, Treasurer, two additional members, the editors of the newsletter and journal, respectively, as well as the business editor of the journal. They meet on a regular basis to conduct the business of ORSSA.
 - A number of honorary memberships of ORSSA have been awarded over the years and include Herbert Sichel, Pat Rivett, Gerhard Rudolph, Jos Grobelaar, Gerhard Geldenhuys, and Mike Splaine. The society also has a retired member category. At the conference in 2003 ORSSA introduced another form of recognition, ORSSA Fellows, for long-standing members and members who have over the years contributed significantly to OR in the country as well as served ORSSA in various ways.
 - ORSSA joined IFORS in 1973 while it is also a member of the Association of European Operational Research Societies (EURO) since the latter is the “closest” regional grouping of IFORS that ORSSA can belong to, given that there is no African grouping.
- All the activities of ORSSA are conducted through voluntary service of members. The membership of ORSSA is relatively small and although the number fluctuates, there are around 300 members mainly in South Africa but also from other countries. It is however, true that there are many more people practicing OR in South Africa but many of them tend to associate themselves with their functional areas of work such as industrial engineering, finance, supply-chain management, information systems, etc.
- A few additional interesting aspects of the society are firstly that the society’s constitution drafted at its inception included specific prohibitions against any discrimination on the grounds of race, gender or creed. This was done at the height of the institutionalized apartheid era [6]. Secondly, members of ORSSA have been involved in international activities, for example, one member was a Vice President of IFORS (Theo Stewart),

an ORSSA member was the editor of the IFORS newsletter for developing countries and is also the current editor of the IFORS newsletter (Hans Ittmann). The chairperson of the adjudication committee for the IFORS prize for developing countries during the past two IFORS conferences is an ORSSA member (Paul Fatti) while a South African entry to this prize has been runner-up on three occasions. One of the more recent Presidents of the International Multi-Criteria Decision Making Society is a member of ORSSA (Theo Stewart). Members from ORSSA regularly contribute to IFORS and EURO conferences although the numbers are small. There is also some involvement with working groups of EURO. The majority of ORSSA members who publish tend to publish in ORiON, the local journal, although a limited number of papers are published in international OR journals. A few books authored by ORSSA members have been published over the years. Another highlight of the South African society was when an entry from the South African National Defence Force (SANDF) won the prestigious Franz Edelman award in 1996. This was for excellent work on “determining the size and shape of the SANDF”, given the absence of a conventional military threat [9]. Support from President Nelson Mandela, then President of the country, in the form of an accompanying letter, cannot be underestimated!

From the above, it is clear that ORSSA is an active society. It is struggling with problems similar to those elsewhere in the world, where it is difficult to retain the more junior members and those finishing at universities.

Presidents of ORSSA to date are listed as follows: Dr H Sichel (1970), Mr JW Grobbelaar (1971), Mr D Masterson (1972), Dr G Rudolph (1973), Mr J Miller (1974),

Mr K Sandrock (1975), Mr HID du Plessis (1976), Mr R Eales (1977), Prof TJ Stewart (1978), Prof JS Wolvaardt (1979), Dr MJ Venter (1980), Dr AH Money (1981), Mr M Splaine (1982), Mr D Masterson (1983), Prof LP Fatti (1984), Mr DW Evans (1985), Mr MA de Vries (1986), Mr HW Ittmann (1987), Prof G Erens (1988–89), Ms A Pachyannis (1990–91), Mr LA Visagie (1992–93), Mrs E Ferreira (1994–95), Dr E Dixon (1996–97), Prof JW Hearne (1998–99), Dr PduT Fourie (2000–01), Mr HW Ittmann (2002–03), Prof WR Gevers (2004–05), Mrs MF Harmse (2006–07), Prof VSS Yadavalli (2008–09).

INTRODUCTION

Scatter search (SS) is an evolutionary method that has been successfully applied to hard optimization problems. SS was first introduced by Prof. Fred Glover as a heuristic for integer programming and it was based on strategies presented at a management science and engineering management conference held in Austin, Texas in September 1967. Unlike genetic algorithms, it operates on a small set of solutions and employs diversification strategies of the form proposed in tabu search [1], which give precedence to strategic learning based on adaptive memory, with limited recourse to randomization.

The fundamental concepts and principles were first proposed in 1977 [2] as an extension of formulations, dating back to the 1960s, for combining decision rules and problem constraints. (The constraint combination approaches, known as *surrogate constraint* methods, now independently provide an important class of relaxation strategies for global optimization.) The SS framework is flexible, allowing the development of alternative implementations with varying degrees of sophistication. In addition, SS can be combined with other methods to enhance their

effectiveness. For example, SS has been integrated with particle swarm optimization and adaptive memory strategies of tabu search to produce a method called *cyber swarm optimization* that has provided improvements over its particle swarm component [3].

As described in Refs 4 and 5, SS consists of five methods:

1. Diversification Generation
2. Improvement
3. Reference Set Update
4. Subset Generation
5. Solution Combination

The *diversification generation method* is used to generate a set of diverse solutions that are the basis for initializing the search. The most effective diversification methods are those capable of creating a set of solutions that balances diversification and quality. It has been shown that SS produces better results when the diversification generation method is not purely random and constructs solutions by reference to both a diversification measure and the objective function.

The *improvement method* transforms solutions with the goal of improving quality (typically measured by the objective function value) or feasibility (typically measured by some degree of constraint violation). The input to the improvement method is a single solution that may or may not be feasible. The output is a solution that may or may not be better (in terms of quality or feasibility) than the original solution. The typical improvement method is a local search (LS) with the usual rule of stopping as soon as no improvement is detected in the neighborhood of the current solution. There is the possibility of basing the improvement method on procedures that use a neighborhood search but that they are able to escape local optimality. tabu search, simulated annealing, and variable neighborhood search qualify as candidates for such a design. This may seem

as an attractive option as a general approach for an improvement method, however, these procedures do not have a natural stopping criterion. The end result is that choices need to be made to control the amount of computer time that is spent improving solutions (by running a metaheuristic-based procedure) versus the time spent outside the improvement method (e.g., combining solutions). In general, LS procedures seem to work well and most SS implementations do not include mechanisms to escape local optimality within the process of improving a solution.

The *reference set update* method refers to the process of building and maintaining a reference set of solutions that are used in the main iterative loop of any SS implementation. While there are several implementation options, this element of SS is fairly independent from the context of the problem. The first goal of the reference update method is to build the initial reference set of solutions from the population of solutions generated with the diversification method. Subsequent calls to the reference update method serve the purpose of maintaining the reference set. The typical design of this method builds the first reference set by blending high quality solutions and diverse solutions. While choosing diverse solution, reference needs to be made to a distance metric that typically depends on the solution representation. That is, if the problem context is such that continuous variables are used to represent solutions, then diversification may be measured with Euclidean distances. Other solution representations (e.g., binary variables or permutations) result in different ways of calculating distances and in turn diversification. The updating of the reference set during the SS iterations is customarily done on the basis of solution quality.

The *subset generation method* produces subsets of reference solutions which become the input to the combination method. The typical implementation of this method consists of generating all possible pairs of solutions. The SS framework considers also the generation of larger subsets of reference solutions; however, most SS implementations have been limited to operate on pairs of solutions. Clearly, no context information is

needed to implement the subset generation method.

The *solution combination method* uses the output from the subset generation method to create new solutions. New trial solutions are the results of combining, typically two but possibly more, reference solutions. The combination of reference solutions is usually designed to exploit problem context information and solution representation. The strategic use of linear combinations of solutions in heuristic search has often been employed for discrete and nonlinear optimization problems, since such uses were first proposed in Ref. 2. Several proposals for combining solutions represented by permutations have also been applied [6]. The strategy known as *path relinking*, originally proposed within the tabu search methodology [1], has also played a relevant role in designing combination methods for SS implementations.

As mentioned above, we will describe both the main SS elements and the advanced search strategies, and use the maximum diversity problem (MDP), [7] to illustrate some implementation details. The MDP consists of selecting a subset of m elements from a set of n elements in such a way that the sum of the distances between the chosen elements is maximized. The definition of distance between elements is customized to specific applications. As mentioned in Refs 8 and 9, the MDP has applications in plant breeding, social problems, ecological preservation, pollution control, product design, capital investment, workforce management, curriculum design, and genetic engineering. In most applications, it is assumed that each element can be represented by a set of attributes. Let s_{ik} be the state or value of the k th attribute of element i , where $k = 1, \dots, K$. Then the distance between elements i and j may be defined as

$$d_{ij} = \sqrt{\sum_{k=1}^K (s_{ik} - s_{jk})^2}.$$

In this case, d_{ij} is simply the Euclidean distance between i and j . The distance values are then used to formulate the MDP as a quadratic binary problem, where variable x_i

 \end{aligned}$$

We finally would like to highlight the SS library provided in Ref. 5. It consists of a C code that implements the search mechanisms that are discussed throughout their book. The C code can be used “as is” to replicate practical illustrations or can be modified and adapted to other optimization problems of interest. Several SS applications have been implemented from that source code.

BASIC SS DESIGN

Laguna [10] summarizes the basic SS framework as follows (Fig. 1). The search starts with the application of the diversification and improvement methods (step 1 in Fig. 1). The typical outcome consists of a set of about 100 solutions that is referred to as the *population* (denoted by P). In most implementations, the diversification generation method is applied first followed by the improvement method. If the application of the improvement method results in the shrinking of the population (due to more than one solution converging to the same local optimum) then the diversification method is applied again until the total number of improved solutions reaches the desired

target. Other implementations construct and improve solutions, one by one, until reaching the desired population size.

The main SS loop is shown in lines 2 to 11 of Fig. 1. The input to the first execution of the reference set update method (step 3) is the population of solutions generated in step 1 and the output is a set of solutions known as the *reference set* (or *RefSet*). Typically, 10 solutions are chosen from a population of 100. The first five solutions are chosen to be the best solutions (in terms of the objective function value) in the population. The other five are chosen to be the most diverse with respect to the solutions in the reference set. If the diverse solutions are chosen sequentially, then the sixth solution is the most diverse with respect to the five best solutions that were chosen first. The seventh solution is the most diverse with respect to the first six, and so on until the tenth one is added to the reference set.

The inner while-loop (lines 4 to 9) is executed as long as at least one reference solution is new in the *RefSet*. A solution is considered new if it has not been subjected to the subset generation (step 5) and combination (step 6) methods. If the reference set contains at least one new solution, the subset generation method builds a list of all the reference solution subsets that will become the input to the combination method. The subset generation method creates new subsets only. A subset is new if it contains at least one new reference solution. This avoids the application of the combination method to the same subset more than once,

which is particularly wasteful when the combination method is completely deterministic. Combination methods that contain random elements may be able to produce new trial solutions even when applied more than once to the same subset of reference solutions. However, this is generally discouraged in favor of introducing new solutions in the reference set by replacing some of the old ones in the rebuilding step (line 10).

The combination method (step 6) is applied to the subsets of reference solutions generated in the previous step. Most combination methods are designed to produce more than one trial solution from the combination of the solutions in a subset. These trial solutions are given to the improvement method (step 7) and the output forms a pool of improved trial solutions that will be considered for admission in the reference set (step 8).

If no new solutions are added to the reference set after the execution of the reference set update method, then the process exits the inner while-loop. The rebuilding step in line 10 is optional. That is, it is possible to implement a SS procedure that terminates the first time that the reference set does not change. However, most implementations extend the search beyond this point by executing a *RefSet* rebuilding step. The rebuilding of the reference set entails the elimination of some current reference solutions and the addition of diverse solutions. In most implementations, all solutions except the best are replaced in this step. The diverse solutions to be added may be either population solutions that have not been used or new solutions constructed with the generation diversification method. Note that only 10 solutions out of 100 are used from the population to build the initial reference set and therefore the remaining 90 could be used for rebuilding purposes.

The process (i.e., the main while-loop in lines 2 to 11) continues as long as the stopping criteria are not satisfied. Possible stopping criteria include number of rebuilding steps or elapsed time. When SS is applied in the context of optimizing expensive black boxes, a limit on the number of calls to the objective function evaluator (i.e., the black box) may also be used as a criterion for stopping.

We now expand our description and provide examples of each of the SS methods.

THE MAXIMUM DIVERSITY PROBLEM

Three of the five SS elements (the diversification-generation, the improvement, and the combination methods) are *problem-dependent* and should be designed specifically for the problem at hand (although it is possible to design “generic” procedures, it is more effective to base the design on the specific idiosyncrasies of the problem setting). The other two, the reference-set-update and the subset-generation methods, are *problem-independent*, and usually follow a standard implementation. In this section, we describe efficient implementations of the three problem-dependent methods for the MDP. In the next section, we cover the two problem-independent methods.

The definition of distance between solutions is a key design issue in SS implementations. Distance is used to measure how diverse one solution is with respect to a set of solutions. Specifically, for the MDP, let x_i^r be the value of the i th variable for the reference solution r (i.e., $r \in \text{RefSet}$). Also let x_i^t be the value of the i th variable for the trial solution t . Then, the distance between the trial solution t and the solutions in the *RefSet* in our SS implementation is defined as

$$\text{distance}(t, \text{RefSet}) = bm - \sum_{r=1}^b \sum_{i: x_i^t = 1} x_i^r.$$

The formula simply counts the number of times that each selected element in the trial solution t appears in the reference solutions and subtracts this value from the maximum possible distance (i.e., bm). The maximum distance occurs when no element that is selected in the trial solution t appears in any of the reference solutions. When choosing solutions to rebuild the reference set, we select the trial solution that has the maximum distance between itself and the solutions currently in the *RefSet*. Since the solutions are added one at a time, the distance calculations have to be updated before the next solution is selected.

Diversification Generation Method

Duarte and Martí [11] proposed a GRASP Hybrid [12] for generating MDP diverse solutions. It is based on randomizing *D*-2, a deterministic destructive heuristic developed by Glover *et al.* [9]. *D*-2 starts with the infeasible solution for which $x_i = 1$ for all i . That is, all n elements are originally selected. In order to reduce the set of selected elements to m , the procedure performs $n-m$ steps. At each step, the procedure deselects element i^* (i.e., x_{i^*} is set to 0), where i^* is such that

$$D(i^*) = \text{Min}_{i: x_i=1} (D(i)),$$

where $D(i) = \sum_j d_{ij}x_j$.

The randomization of *D*-2 that is employed within *RD*-2 consists of selecting i^* from a reduced candidate list formed by all those elements i such that $D(i) \leq (1 + \alpha)D(i^*)$. The value of α is initially set to 0.5 and decreased by 0.1—to a minimum of 0.1—after a prespecified CPU time is consumed without improving the incumbent. We set this value to a 20% of the total CPU time in our implementation.

Improvement Method

The LS method [13] scans the set of selected elements in search of the best exchange to replace a selected element with an unselected one. The method performs moves as long as the objective value increases and it stops when no improving exchange can be found. The improved local search method, *I_LS*, [11] selects the element i^* ($x_{i^*} = 1$) that provides the smallest contribution to the objective function value of the current solution. Then, it searches for an element j ($x_j = 0$) to be exchange with element i^* . The first element j that results in an improving move is selected and the exchange is performed without examining the remaining unselected elements. If no improving move can be found to exchange element i^* , then the selected element with the next smallest contribution is examined. This process continues until no improving exchange can be found.

Combination Method

This method consists of the application of the destructive heuristic *D*-2 [9] to the union

of the elements in the reference solutions being combined. The method starts with the selection of all elements in the union and then it deselects one element at a time until there are only m selected elements remaining. The element i that is deselected at each step is the one with the minimum $D(i)$ value.

PROBLEM-INDEPENDENT METHODS

We now discuss some generic (i.e., context-independent) implementations of the reference set update and the subset generation. While these designs are not customized for a particular problem setting, the solution representation (e.g., binary strings, permutations, real numbers, etc.) does play an important role in their development and implementation. The following two sections have been taken from Ref. 10.

Reference Set Update

The execution of the diversification generation and improvement methods in line 1 of Fig. 1 results in a population P of solutions. The reference set update method is executed in two different parts of the SS procedure. The first time that the method is called, its goal is to produce the initial *RefSet*, consisting of a mix of b (typically 10) high quality and diverse solutions drawn from P . The mix of high quality and diverse solutions could be considered a tunable parameter; however, most implementations populate the initial reference set with half of the solutions chosen by quality and half chosen by diversity.

Choosing solutions by quality is straightforward. From the population P , the best (according to the objective function value) $b/2$ solutions are chosen. These solutions are added to *RefSet* and deleted from P . To choose the remaining half, an appropriate measure of distance $d(r, p)$ is needed, where r is a reference solution and p is a solution in P . The distance measure depends on the solution representation, but must satisfy the usual conditions for a metric, that is

$d(r, p) = 0$	If and only if $r = p$
$d(r, p) = d(p, r) > 0$	If $r \neq p$
$d(r, q) + d(q, p) \geq d(r, p)$	Triangle inequality

For instance, the Euclidean distance is commonly used when solutions are represented by continuous variables

$$d(r, p) = \sqrt{\sum_{i=1}^n (r_i - p_i)^2}.$$

Likewise, the [14] distance is appropriate for two strings of equal length. The distance is given by the number of positions for which the corresponding symbols are different. In other words, the distance is the number of changes required to transform one string into the other

$$d(r, p) = \sum_{i=1}^n v_i \quad v_i = \begin{cases} 0 & r_i = p_i \\ 1 & r_i \neq p_i \end{cases}. \quad (1)$$

This distance has been typically used for problems whose solution representation is given by binary vectors (e.g., the max-cut and knapsack problems) and permutation vectors (e.g., the traveling salesman, quadratic assignment, and linear ordering problems).

The distance measure is used to calculate the minimum distance $d_{\min}(p)$ of a population solution and all the reference solutions r

$$d_{\min}(p) = \min_{r \in \text{RefSet}} d(r, p).$$

Then, the next population solution p to be added to *RefSet* and deleted from P is the one with the maximum $d_{\min}$ value. That is, we want to choose the population solution p^* that has the maximum minimum distance between itself and all the solutions currently in *RefSet*

$$p^* = \left\{ p : \max_{p \in P} d_{\min}(p) \right\}.$$

The process is repeated $b/2$ times to complete the construction of the initial *RefSet*. Note that after the first calculation of the $d_{\min}$ values, they can be updated as follows. Let

p^* be the population solution most recently added to the *RefSet*. Then, the $d_{\min}$ value for a population solution p is given by

$$d_{\min}(p) = \min(d_{\min}(p), d(p, p^*)).$$

Alternatively, the diverse solutions for the initial reference set may be chosen by solving the MDP introduced above. The special version of the MDP that must be solved includes a set of elements that have already been chosen (i.e., the high quality solutions). Mathematically, the problem may be formulated as follows:

$$\begin{aligned} & \text{Maximize} && \sum_{(p, p^*) \in P: p \neq p'} d(p, p') x_p x_{p'} \\ & \text{Subject to} && \sum_{p \in P} x_p = b \\ & && x_p = 1 \quad \forall p \in \text{RefSet} \\ & && x_p \in \{0, 1\} \quad \forall p \in P. \end{aligned}$$

The formulation assumes that a subset of high quality solutions in P have already been chosen and added to *RefSet*. The binary variables indicate whether a population solution p is chosen ($x_p = 1$) or not ($x_p = 0$). The second set of constraints in the formulation force the high-quality solutions to be included in the set of b solutions that will become the initial *RefSet*. This nonlinear programming model has been translated into an integer program for the purpose of solving it as well as for showing that the MDP is NP-hard. Martí *et al.* [15] embed the MDP in a SS procedure for the max-cut problem. Instead of solving the MDP exactly, they employ the GRASP_C2 procedure developed by Duarte and Martí [11]. The procedure was modified to account for the high-quality solutions that are chosen before the subset of diverse solutions is added to the *RefSet*. The procedure is executed for 100 iterations and the most diverse *RefSet* is chosen to initiate the SS.

The reference set update method is also called in step 8 of Fig. 1. This step is performed after a set of one or more trial solutions has been generated by the sequential calls to the subset generation, combination,

and improvement methods (see steps 5, 6, and 7 in Fig. 1). The most common update consists of the selection of the best (according to the objective function value) solutions from the union of the reference set and the set of trial solutions generated by steps 5–7 in Fig. 1. Other updates have been suggested in order to preserve certain amount of diversity in the *RefSet*. These advanced updating mechanisms are beyond the scope of this tutorial article but the interested reader is referred to Chapter 5 of Ref. 5 for a detailed description and to Ref. 16 for experimental results.

Subset Generation

This method is in charge of proving the input to the combination method. This input consists of a list of subsets of reference solutions. The most common subset generation consists of creating a list of all pairs (i.e., all 2-subsets) of reference solutions for which at least one of the solutions is new. A reference solution is new if it has not been used by the combination method. The first time that this method is called (step 5 in Fig. 1), all the reference solutions are new, given that the method is operating on the initial *RefSet*. Therefore, the execution of the subset generation method results in the list of all 2-subsets of reference solutions, consisting of a total of $(b^2 - b)/2$ pairs. Because the subset generation method is not based on a sample but rather on the universe of all possible pairs, the size of the *RefSet* in SS implementation must be moderate (e.g., less than 20). As mentioned in the introduction, a typical value for b is 10, resulting in 45 pairs the first time that the subset generation method is executed.

When the inner while-loop (steps 5–8 in Fig. 1) is executing, the number of new reference solutions at the time that the subset generation method is called depends on the strategies implemented in the reference set update method. Nonetheless, the number of new solutions decreases with the number of iterations within the inner while-loop. Suppose that b is set to 10 and that, after the first iteration of the inner while-loop, six solutions are replaced in the reference set. This means that the reference set that will serve

as the input to the subset generation method will consist of four “old” solutions and six “new” solutions. Then, the output of the subset generation method will be 39 2-subsets. In general, if the reference set contains n new solutions and m old ones, the number of 2-subsets that the subset generation method produces is given by

$$nm + \frac{n^2 - n}{2}.$$

The SS methodology also considers the generation of subsets with more than two elements for the purpose of combining reference solutions. As described in Ref. 5, the procedure uses a strategy to expand pairs into subsets of larger size while controlling the total number of subsets to be generated. In other words, the mechanism does not attempt to create all 2-subsets, then all 3-subsets, and so on, until reaching the $b-1$ -subsets and finally the entire *RefSet*. This approach would not be practical because there are 1013 subsets in a reference set of size $b = 10$. Even for a smaller reference set, combining all possible subsets would not be effective because many subsets will be very similar. For example, a subset of size four containing solutions 1, 2, 3, and 4 is almost the same as all the subsets with four solutions for which the first three solutions are solutions 1, 2, and 3. And even if the combination of subset {1, 2, 3, 5} would generate a different solution than the combination of subset {1, 2, 3, 6}, these new trial solutions would likely reside in the same basin of attraction and therefore converge to the same local optimum after the application of the improvement method. Instead, the approach selects representative subsets of different sizes by creating subset types:

- *Subset Type*. all 2-element subsets;
- *Subset Type*. 3-element subsets derived from the 2-element subsets by augmenting each 2-element subset to include the best solution not in this subset;
- *Subset Type*. 4-element subsets derived from the 3-element subsets by augmenting each 3-element subset to include the best solutions not in this subset;

- *Subset Type*. the subsets consisting of the best i elements, for $i = 5$ to b .

Campos *et al.* [17] designed an experiment with the goal of assessing the contribution of combining subset types 1 to 4 in the context of the linear ordering problem. The experiment undertook to identify how often, across a set of benchmark problems, the best solutions came from combinations of reference solution subsets of various sizes. The experimental results showed that most of the contribution (measured as the percentage of time that the best solutions came from a particular subset type) could be attributed to subset type 1. It was acknowledge, however, that the results could change if the subset types were generated in a different sequence. Nonetheless, the experiments indicate that the basic SS that employs only subsets of type 1 is quite effective and explains why most implementations do not use subset types of higher dimensions.

HYBRIDIZING SCATTER SEARCH WITH TABU SEARCH

Evolutionary approaches, such as SS, implicitly make use of memory. This is evident if one examines how the reference set update, solution combination, and subset generation methods operate. The reference set update method, in its most basic form, is designed to “remember” the best solutions encountered during the search. Some features of these solutions are used to create new trial solutions with the combination method. Hence, this method is instrumental in the transmission of information embedded in the reference solutions. But we can add extra memory structures to SS by hybridizing it with tabu search. Specifically, in this section, we briefly describe how to design tabu search based procedures to implement the diversification generation, the improvement and the combination methods for the MDP.

Diversification Generation Method

The diversification generator within the tabu search methodology, *MD-2*, is also based on

the destructive procedure *D-2*. At each step of the procedure, the element i^* to be deselected is such that

$$D(i^*) = \min_{i:x_i=1} \left(D(i) - \beta(range) \left(\frac{f(i)}{f_{\max}} \right) + \delta(range) \left(\frac{q(i)}{q_{\max}} \right) \right),$$

where

$$range = \max_{i:x_i=1} (D(i)) - \min_{i:x_i=1} (D(i)).$$

In this modified distance calculation, $f(i)$ indicates the frequency in which element i has appeared in previous solutions and $q(i)$ is the average quality (as measured by the objective function value) of past solutions that included element i . The $f_{\max}$ and $q_{\max}$ are the maximum values of f and q over all elements. The penalty factors β and δ are respectively set to 0.1 and 0.0001 according to Gallego *et al.* [7].

Improvement Method

LS_TS [11] implements a short-term tabu search method also based on exchanges. An iteration of this method begins with a random selection of an element i ($x_i = 1$). The probability of selecting element i is inversely proportional to $D(i)$. The list of unselected elements is scanned and the first improving move that exchanges elements i and j ($x_j = 0$) is selected. If no improving move is found, then the least nonimproving move is chosen. The chosen exchange is performed and both elements participating in the exchange are classified tabu-active for a number of iterations (known as the *tabu tenure*). Tabu-active elements are not allowed to participate in any exchanges. The LS_TS method stops if after a number of consecutive iterations the incumbent solution is not modified.

Combination Method

This method consists of the application of the *MD-2* procedure to the union of the elements of the reference solutions being

combined. This method uses information about solutions generated in the past as well as information associated with those solutions combined in previous iterations. Once we obtain the set of elements selected in the solutions being combined, we only need to apply *MD-2* with the modified evaluations according to the penalty terms

$$\beta(\text{range}) \left(\frac{f(i)}{f_{\max}} \right) \text{ and } \delta(\text{range}) \left(\frac{q(i)}{q_{\max}} \right).$$

The element with minimum D value is deselected. The union of elements updated, iteration are performed until the number of selected elements matches m .

- SOM** This data set consists of 20 matrices with random numbers between 0 and 9 generated from an integer uniform distribution. The problem sizes are such that for $n = 100, m = 10, 20, 30$, and 40; for $n = 200, m = 20, 40, 60$, and 80; for $n = 300, m = 30, 60, 90$, and 120; for $n = 400, m = 40, 80, 120$, and 160; and for $n = 500, m = 50, 100, 150$, and 200. These instances were generated by Silva *et al.* [18].
- GKD** This data set consists of 20 matrices for which the values were calculated as the Euclidean distances from randomly generated points with coordinates in the 0 to 10 range. The number of coordinates for each point is also randomly generated between 2 and 21. Glover *et al.* [9] developed this data generator and constructed instances with $n = 30$. We generated instances with $n = 500$ and $m = 50$.
- Type I** Diversity values are real numbers uniformly distributed between 0 and 1000. We generate 30 instances of Type I with $n = 500, 2000$ and $m = 50, 200$.
- Type II** Diversity values are real numbers uniformly distributed between 0 and 10. We generate 20 instances of Type II, as described in the section titled “Basic SS Design,” with $n = 500$ and $m = 50$.

The purpose of the first experiment is identifying the most effective method for generating subsets of reference solutions that are in turn the input to the combination method. For this experiment, we consider combinations of 2, 3, 4, and 5 solutions. Our subset generation method operates as described in the section titled “Problem-Independent Methods.” All subsets of size 2 (SG1) are considered. That is, all pairs of reference solutions are added to the list of subsets. Subsets of size 3 (SG2) are constructed by considering each subset of size 2 and adding the best reference solution that is not part of

EXPERIMENTS WITH THE MAXIMUM DIVERSITY PROBLEM

In this section, we summarize some of the experiments presented in Ref. 7 for the MDP. The SS implementation follows the basic framework outlined in Fig. 1. The diversification generation, combination, and improvement methods are those corresponding to the descriptions in the section titled “The Maximum Diversity Problem.” All the experiments were conducted on a Pentium 4 computer at 3 GHz with 3 GB of RAM. The procedures were coded in Java and executed in the Java Runtime Environment 1.5. We use the same four data sets employed in Ref. 11.

the subset. Subsets of higher dimensions are constructed following the same logic. That is, subsets of size 4 (SG3) are based on subsets of size 3. Likewise, subsets of size 5 (SG4) are constructed by adding a solution to subsets of size 4. This mechanism avoids the exponential explosion in the number of subsets generated had we considered all possible subsets of size 3, 4, and 5. The results of running this experiment on 20 instances (10 problems of each type, I and II, and with $n = 500$ and $m = 50$) are summarized in Table 1. We use the outcomes of our experiments to calculate the average percent deviation (*average*

Table 1. Alternative Subset Generation Methods

Subset Generation Method	Average Deviation (%)	Number of Best
SG1	0.0000	20
SG2	0.0017	19
SG3	0.0000	20
SG4	0.0042	18

deviation) of the solutions obtained by each procedure when compared to the best solutions during the given experiments. We also report on the number of best solutions (*number of best*) found by each method.

The results of this preliminary experiment indicate that there is no additional gain that could be realized by generating and combining subsets with more than 2 solutions. Hence, we perform step 2 (Fig. 1) of the SS implementation by limiting the subset generation to all pairs of reference solutions. These results are in line with similar experiments for other combinatorial optimization problems [17].

The objective of the second experiment is to compare the relative merit of the SS variants described in the sections titled “The Maximum Diversity Problem” and “Hybridizing Scatter Search with Tabu Search,” respectively. We set a time limit of 3 CPU min and we run each procedure with and without the improvement method. The results are summarized in Table 2.

The results in Table 2 indicate the advantage of using an improvement method within our design. In terms of average deviation from the best solutions, the improvement method has the largest impact in the case of the base design. Also, the improvement method makes a significant difference in the number of best solutions found in the tabu search hybrid. In general, we conclude that the procedures embedded in the tabu search hybrid variant results in the best SS configuration. For the next experiment, the SS that we use is the one that implements the tabu search hybrid procedures (including the improvement method), as described in the section titled “Hybridizing Scatter Search with Tabu Search.”

In the final experiment, we compare the proposed procedure to state-of-the-art methods for solving the MDP. In particular we consider

- KLD [18] with LS [13]
- KLDv2 [18] with LS [13]
- Tabu_D–2 with LS_TS [11]

In this experiment, we observed the solution quality obtained by each method after 30 s and after 3 min of search time. Table 3 reports the average percentage deviation of the solution obtained with each method with respect to the best solution known.

Table 3 shows the merit of the proposed procedure. The SS implementation consistently produces the best solutions with percent deviations that in some cases are orders of magnitude smaller than those of the competing methods. The problem instances in the GKD set do not provide a way of differentiating the performance of the methods that we are comparing. They are either easy to solve and all the methods are capable of finding the optimal solutions in a very short period of time or the problems are difficult and all the methods are attracted to the same local optima.

CONCLUSIONS

Our goal was to introduce the SS framework at a level that would make it possible for the reader to implement a basic but robust procedure. A number of extensions are possible and some of them have already been explored and reported in the literature. It is not possible within the limited scope of this encyclopedic article to detail completely many of the aspects of SS that warrant further investigation. Additional implementation considerations, including those associated with intensification and diversification processes, and the design of accompanying methods to improve solutions produced by combination strategies are found in several of the references listed below.

THE SEARCH ALLOCATION GAME

INTRODUCTION

An ultimate purpose of *search theory* is to answer how efficiently we could find targets. In search theory, there are two main players: searchers and targets. As *operations research* (OR) was born in World War II as a realistic academia, search theory originated from the military research of the Anti-Submarine Warfare Operations Research Group (ASWORG) of the U.S. Navy for anti-submarine warfare (ASW). The famous books *Methods of Operations Research* by Morse and Kimball [1] and *Search and Screening* by Koopman [2] transmitted the fruitful methodology of OR to the world. In Koopman's book, he has discussed in one of his chapters on how to distribute a limited amount of time in two regions for an effective search. He made a big contribution to the theoretical progress of search theory, being conscious of the important role of optimization in OR.

Koopman submitted some articles to the early editions of *OR* and developed his theory on optimal distribution of searching effort or searching resource. In Ref. 3 published in 1953, he focused on search in two areas and generalized the theory in Ref. 4, entitled "The theory of search ‡V: The optimum distribution of searching effort." The origin of many optimization problems arising afterward in the field of search theory is Koopman's problem, which are discussed below.

Let us consider the set of all real numbers $\mathbf{R}$ as a search space. A target hides at a position $x \in \mathbf{R}$ with probability density $p(x)$, where nonnegative $p(x)$ satisfies

$\int_{\mathbf{R}} p(x)dx = 1$. A searching resource or an effort means any kind of resource to be useful for search, such as search time, sensors, and manpower. Let $\varphi \equiv \{\varphi(x), x \in \mathbf{R}\}$ be a distribution plan, where $\varphi(x)$ is the resource density to be distributed at x . If the target is at x and the resource density $\varphi(x)$ is distributed there, the searcher can detect the target with probability $1 - \exp[-\varphi(x)]$. What is an optimal distribution plan of the total amount of resource Φ to make the detection probability the largest? This problem is formulated as follows:

$$(K_c) \quad \max_{\{\varphi(x)\}} P[\varphi] \equiv \int_{\mathbf{R}} p(x) \{1 - \exp[-\varphi(x)]\} dx$$

$$\text{s.t.} \quad \int_{\mathbf{R}} \varphi(x)dx = \Phi, \quad \varphi(x) \geq 0, \quad x \in \mathbf{R}. \quad (1)$$

From the necessary condition of optimality $P(\varphi + \delta\varphi) - P(\varphi) \leq 0$ for an optimal solution φ and any little perturbed solution $\varphi + \delta\varphi$, Koopman derived an optimal solution φ^* . We can easily reach his conclusion that $p(x)\exp[-\varphi(x)] = \lambda(\text{const.})$ if $\varphi(x) > 0$, by applying calculus of variations to the variational problem (K_c) , in which we maximize the functional $F(\varphi, x) \equiv p(x)\{1 - \exp[-\varphi(x)]\}$ under Equation 1. The calculus says that an optimal function φ^* is given by the Euler–Lagrange characteristic equation $d[F(\varphi, x) - \lambda\varphi(x)]/d\varphi = 0$, where λ is a Lagrangean multiplier.

We can define Koopman's problem in a discrete cell space, as follows. For a target that is estimated to be in cells $i = 1, 2, \dots, n$ with respective probability $p_i (p_i \geq 0, \sum_i p_i = 1)$, how should we distribute Φ searching resources in an optimal manner to maximize the detection probability of the target? Our question is formulated by

$$(K_d) \quad \max_{\{\varphi_i\}} P(\varphi) = \sum_{i=1}^n p_i [1 - \exp(-\varphi_i)]$$

$$\text{s.t.} \quad \sum_{i=1}^n \varphi_i = \Phi, \quad \varphi_i \geq 0, \quad i = 1, \dots, n.$$

To deal with such optimization problems, we already have a good methodology such as convex analysis and nonlinear programming. Koopman's problem is also the first step for more general field of research named *optimal resource allocation problems* [5]. de Guenin [6] generalized Koopman's problem to a variational problem and Kadane [7] extended it to a discrete optimization problem with discrete resources.

In *Methods of Operations Research*, the authors had already considered the problem of how to intercept the passage of a submarine in straits by an ASW-airplane, modeling it as a two-player game. But such a two-sided problem is exceptional. After Koopman, there have been many studies dealing with one-sided problems for an optimal search given that the searcher knows the probabilistic law of target existence, as in Koopman's problem. From search problems with stationary targets, search theory steps forward to problems with moving targets. Stone developed a theoretical analysis of stationary target problems in a book, named *Theory of Optimal Search* [8] and won the Lanchester Prize.

As an early research on the moving target problem, there is Pollock's work [9], where he discussed an optimal search for target hiding and moving in two cells, and other research such as Dobbie [10], Hellman [11], Iida [12], and Kan [13]. Brown [14] proposed a numerical algorithm to compute an optimal distribution of searching resource, which varies on a discrete time horizon, to maximize the total detection probability. Washburn [15] extended Brown's method to a discrete resource problem. This was generalized by Stromquist and Stone [16]. From the point of view of optimization, their methods belong to convex optimization and global optimization for continuous objectives. Eagle and Yee [17] and Hohzaki and Iida [18] apply branch-and-bound methods or relaxation methods to search problems with constraints on the searcher's motion.

In the research surveyed so far, the authors do not regard the target existence or the target movement as the decision making of the target but as stochastic parameters, and discuss their problems as one-sided problems. The one-sided search problem

progresses to a two-sided problem, namely a search game, where the target is a decision maker as well as the searcher. Search games can be split into two categories, depending on the strategy of searcher: the distribution of searching resource or the movement in a search space. The former is referred to as *search allocation game* (SAG) [19]. The latter can be split into two further categories. We refer to the problem with stationary targets as the *hide-and-search game* (HSG) and the one with moving targets as the *evasion-and-search game* (ESG). For targets, almost all research takes the moving strategy, assuming that the target's mobility is much inferior to the searcher's, as seen in the ASW operation between submarines and ASW airplanes. Some researchers take exceptional models such as Baston and Garnaev [20] and the *Blotto game* [21], where the searcher and the target adopt the same type of strategy to distribute their resources or forces to overwhelm their opponents.

Norris [22] studied a two-person zero-sum search game whose payoff is the number of searches until the detection of the target. The searcher repeatedly looks in several boxes but possibly overlooks the target even though the target is there. Norris' problem is regarded as an SAG with discrete resource. Nakai [23] and Iida *et al.* [24] discussed single-stage SAGs and Kikuta [25] dealt with a single-stage HSG. Baston and Bostock [26] and Garnaev [27] analyzed an optimal strategy of an ASW helicopter to drop mines to destroy a hiding submarine as a single-stage ESG. Danskin [28] discussed the dipping strategy of sound buoys for an ASW airplane to detect a submarine moving diffusively in a two-dimensional plane. Because the submarine takes a fixed course and speed, he deals with the problem as an HSG on the plane called *speed circle*. We can take Eagle and Washburn [29] as another example of single-stage ESGs with moving searcher. Meinardi [30] discussed a competition between a searcher and a target as a multistage ESG. Both players are moving on a line. As the payoff, Washburn [31] and Nakai [32] adopt the total traveling distance of the searcher until detection of the target, which happens on the coincidence of cells selected by the searcher

and the target. Alpern [33], Gal [34,35], and Alpern and Gal [36] are big contributors to the HSG and the ESG.

We have taken an overview of the literatures on the search problem since Koopman began search theory. Koopman's formulation for an optimal distribution of resource is compatible with formulations in general optimization problems and therefore we can use the basics of nonlinear programming such as convex programming to solve the SAG. Unlike the SAG, the HSG and the ESG more likely belong to discrete optimization problem and they require special idea or customization to be solved. There are many differences between the SAG and the (H/E)SG from the methodological point of view. We focus on SAG in the following sections.

SAG FOR A STATIONARY TARGET

Let us consider the following two-person zero-sum game with a hiding target and a searcher.

- A search space consists of n cells, $\mathbf{K} = \{1, 2, \dots, n\}$, and a target hides in one of them.
- A searcher distributes Φ continuously divisible searching resources into the cells to detect the hiding target.
- If the target is in i and x searching resources are scattered there, the searcher detects the target with probability $f_i(x) \equiv 1 - \exp(-\alpha_i x)$, where α_i indicates the effectiveness of unit resource in cell i on detection.

The searcher wants to maximize the detection probability and the target desires to minimize it.

Let us denote a mixed strategy of the target by $\mathbf{p} = \{p_i, i \in \mathbf{K}\}$, where p_i is the probability with which the searcher hides in cell i . A pure strategy of the searcher is denoted by $\mathbf{x} = \{x_i, i \in \mathbf{K}\}$. x_i is the quantity of resource to be distributed in cell i . We have the expression for the expected detection probability, $P(\mathbf{x}, \mathbf{p}) = \sum_i p_i [1 - \exp(-\alpha_i x_i)]$.

We can see that there exists an equilibrium point, $\mathbf{x}^*$ and $\mathbf{p}^*$, for our search game

from known properties of the so-called convex game [37] because $P(\mathbf{x}, \mathbf{p})$ is strictly concave for $\mathbf{x}$. The following solution satisfies the optimality conditions of $\mathbf{x}^* = \arg \max P(\mathbf{x}, \mathbf{p}^*)$ and $\mathbf{p}^* = \arg \min Q(\mathbf{x}^*, \mathbf{p})$.

$$x_i^* = \frac{1/\alpha_i}{\sum_{j \in \mathbf{K}} 1/\alpha_j} \Phi, p_i^* = \frac{1/\alpha_i}{\sum_{j \in \mathbf{K}} 1/\alpha_j}.$$

As a result, the optimal strategies x_i and p_i look simple in such a manner that they are proportional to the reciprocal of α_i . An optimal solution of the one-sided problem $\max_{\mathbf{x}} P(\mathbf{x}, \mathbf{p})$ with fixed $\mathbf{p}$ is given by $x_i^* = [\log(\alpha_i p_i / \lambda)]^+ / \alpha_i$, where $[x]^+ \equiv \max\{0, x\}$ and λ is a Lagrangean multiplier. It often happens that the solution of the game is simpler than the solution of the one-sided optimization problem.

SAG FOR A MOVING TARGET

Here we discuss an SAG with a moving target. Although we consider time in our model, we define our SAG in a discrete geographic space and a discrete time space, as in the section titled "SAG for a Stationary Target."

- B1. Let us denote a search space by $\mathbf{K} \times \mathbf{T}$ consisting of a discrete cell space $\mathbf{K} = \{1, \dots, n\}$ and a discrete time space $\mathbf{T} = \{1, \dots, T\}$.
- B2. Let us denote a set of target paths by Ω , which is a set of functions from $\mathbf{T}$ to $\mathbf{K}$. A target chooses one from the set and follows it as time passes by. A path $\omega \in \Omega$ runs in cell $\omega(t) \in \mathbf{K}$ at time $t \in \mathbf{T}$.
- B3. A searcher wants to detect the target using searching resource at hand. $\Phi(t)$ is the amount of resource available at time t . The searcher can start the search from time τ .
- B4. If the target is in cell i and the searcher distributes x searching resources there, the searcher detects the target with probability $1 - \exp(-\alpha_i x)$. An event of no-detection at a time is exclusive to events at other time points.
- B5. The searcher acts as a maximizer and the target as a minimizer for the detection probability.

Let us denote a searcher's strategy by $\varphi = \{\varphi(i, t), i \in \mathbf{K}, t \in \hat{\mathbf{T}}\}$ during a time interval $\hat{\mathbf{T}} = \{\tau, \tau + 1, \dots, T\}$ starting from τ . $\varphi(i, t) \in \mathbf{R}$ is the amount of resource which the searcher distributes in cell i at time t . We denote a mixed strategy of the target by $\pi = \{\pi(\omega), \omega \in \Omega\}$. $\pi(\omega)$ is the selection probability for path $\omega \in \Omega$.

For a target path ω and a searcher's strategy φ , the detection probability is given by

$$P(\varphi, \omega) = 1 - \exp \left[- \sum_{t=\tau}^T \alpha_{\omega(t)} \varphi(\omega(t), t) \right], \quad (2)$$

which is the payoff of the game, and its expectation $P(\varphi, \pi) = \sum_{\omega} \pi(\omega) P(\varphi, \omega)$ is to be maximized for the searcher and minimized for the target. Because the expected payoff is linear for π and strictly concave for φ , its maximin value coincides with its minimax value, as for the SAG with stationary targets. The maximin optimization gives us an optimal searcher strategy φ^* and the minimax optimization gives an optimal mixed strategy for the target π^* . An equilibrium point of the game has a much simpler form than an optimal solution of the one-sided problem $\max_{\varphi} P(\varphi, \pi)$. While the solution of the one-sided problem can be calculated by Brown's algorithm [14] or Washburn's algorithm [15] using nonlinear programming, an optimal searcher strategy of the search game is given by the following linear programming problem:

$$\begin{aligned} (P_S) \quad & \max_{\varphi} \eta \\ \text{s.t.} \quad & \sum_{t=\tau}^T \alpha_{\omega(t)} \varphi(\omega(t), t) \geq \eta, \omega \in \Omega, \\ & \sum_{i \in \mathbf{K}} \varphi(i, t) \leq \Phi(t), t \in \hat{\mathbf{T}}, \\ & \varphi(i, t) \geq 0, i \in \mathbf{K}, t \in \hat{\mathbf{T}}. \end{aligned}$$

An optimal strategy of the target, π^* , is given by the following linear programming

formulation:

$$\begin{aligned} (P_T) \quad & \min_{\{\pi(\omega), \pi(\omega)\}} \sum_{t \in \hat{\mathbf{T}}} \Phi(t) v(t) \\ \text{s.t.} \quad & \alpha_i \sum_{\omega \in \Omega_{it}} \pi(\omega) \leq v(t), i \in \mathbf{K}, t \in \hat{\mathbf{T}}, \\ & \sum_{\omega \in \Omega} \pi(\omega) = 1, \pi(\omega) \geq 0, \omega \in \Omega, \end{aligned}$$

where Ω_{it} is a set of paths going through cell i at time t , namely, $\Omega_{it} \equiv \{\omega \in \Omega | \omega(t) = i\}$. Problems (P_S) and (P_T) are dual to each other and we can obtain the value of the original search game by calculating $1 - \exp(-\eta^*)$ using the optimal value η^* of the above problems (P_S) or (P_T) . As seen from the formulations (P_S) and (P_T) , we can change the exponential form of payoff $P(\varphi, \omega)$ to the linear form $R(\varphi, \omega) \equiv \sum_{t \in \hat{\mathbf{T}}} \alpha_{\omega(t)} \varphi(\omega(t), t)$ without loss of generality. The equilibrium point of the SAG is more easily computed than that of the one-sided problem.

ENERGY CONSTRAINTS ON TARGET MOTION AND LARGE-SIZE OF PROBLEMS

Real moving targets always have their constraints of motion in the real world. One of them is energy for moving. If the target is a battery-powered submarine, a captain would always be worrying about the energy of the battery to maintain the submarine's mobility. The energy constraints are implicitly involved in the formulations (P_S) and (P_T) such that all paths Ω are enumerated taking account of the constraints. But we have to think over the solution feasibility of the formulation in terms of the total number of paths. If the target can move to any of the n cells of $\mathbf{K}$ each time, we can count the total number of paths as n^T , which is too many to solve the problems (P_S) or (P_T) in feasible computational time. Let us explicitly express the energy constraints for path ω , as follows:

$$\omega(1) \in S_0, \quad (3)$$

$$\omega(t+1) \in N(\omega(t), t), t = 1, \dots, T-1, \quad (4)$$

$$\sum_{t=1}^{T-1} \mu(\omega(t), \omega(t+1)) \leq e_0. \quad (5)$$

Cells $S_0 \subseteq \mathbf{K}$ are possible areas where the target is at initial time $t = 1$. $N(i, t) \subseteq \mathbf{K}$ are cells which the target can move to from cell i at time t and $\mu(i, j)$ is the energy which the target requires to move from cell i to j . e_0 is the initial energy of the target. If the target uses it up, it must stop at the last cell it reaches.

Assuming that function $\mu(i, j)$ is integer-valued, we denote the whole energy states of the target by $\mathbf{E} = \{0, \dots, e_0\}$. Each state of the target is represented by a triplet (i, t, e) , which means that it has residual energy e in cell i at time t . Let us define new variables $q(i, t, e)$ as the probability that the target is in state (i, t, e) and $v(i, j, t, e)$ as the probability that the target is in state (i, t, e) and moves to cell j at time $t + 1$. In the formulations proposed below, we take the variables $\{q(i, t, e)\}$ and $\{v(i, j, t, e)\}$ as the target strategy while $\{\varphi(i, t)\}$ still represents the searcher's strategy. It is easy to construct the strategy $q(\cdot)$ and $v(\cdot)$ from original strategy $\{\pi(\omega)\}$ and reversely transform them. But we omit them.

As stated before, let $R(\varphi, \omega) = \sum_{t \in \mathbf{T}} \alpha_{\omega(t)} \varphi(\omega(t), t)$ be a newly defined payoff function and let variable $h(t)$ be the maximum expected payoff obtained by some optimal search after time t . As reachable cells from state (i, t, e) are denoted by $N(i, t, e) = \{j \in N(i, t) | \mu(i, j) \leq e\}$, the cells from which the target comes into state (i, t, e) at time t are given by $N^*(i, t, e) = \{j \in \mathbf{K} | i \in N(j, t - 1, e + \mu(j, i))\}$. The following dynamic programming (DP) equation is valid for $h(t)$. We can regard the formulation as an optimization problem with respect to the probability flow of target existence.

$$\begin{aligned} h(t) &= \max_{\varphi \in \Psi} \left\{ \sum_{i \in \mathbf{K}} \alpha_i \varphi(i, t) \sum_{e \in \mathbf{E}} q(i, t, e) + h(t + 1) \right\} \\ &= \Phi(t) \max_{i \in \mathbf{K}} \left(\alpha_i \sum_{e \in \mathbf{E}} q(i, t, e) \right) + h(t + 1). \end{aligned}$$

After some consideration, we obtain a linear programming formulation to give us the minimax value of the game and an optimal

target strategy q^* and v^* .

$$\begin{aligned} (E_T) \quad & \min h(\tau) \\ \text{s.t.} \quad & h(t) \geq \Phi(t) \alpha_i \sum_{e \in \mathbf{E}} q(i, t, e) + h(t + 1), \\ & i \in \mathbf{K}, t = \tau, \dots, T - 1, \\ & h(T) \geq \Phi(T) \alpha_i \sum_{e \in \mathbf{E}} q(i, T, e), i \in \mathbf{K}, \\ & q(i, t, e) = \sum_{j \in N(i, t, e)} v(i, j, t, e), \\ & i \in \mathbf{K}, t = 1, \dots, T - 1, e \in \mathbf{E}, \\ & q(i, t, e) = \sum_{j \in N^*(i, t, e)} v(j, t - 1, e + \mu(j, i)), \\ & i \in \mathbf{K}, t = 2, \dots, T, e \in \mathbf{E}, \\ & \sum_{i \in S_0} q(i, 1, e_0) = 1, \\ & \sum_{i \in \mathbf{K}} \sum_{e \in \mathbf{E}} q(i, t, e) = 1, t \in \mathbf{T}, \\ & q(i, 1, e) = 0, i \in \mathbf{K}, e \in \mathbf{E} - \{e_0\}, \\ & q(i, 1, e) = 0, i \in \mathbf{K} - S_0, e \in \mathbf{E}, \\ & v(i, j, t, e) \geq 0, \\ & i, j \in \mathbf{K}, t = 1, \dots, T - 1, e \in \mathbf{E}. \end{aligned}$$

We can derive the other linear programming problem, say (E_S) , for an optimal searcher strategy by the DP formulation for the maximin optimization in the same manner to the derivation of (E_T) (see Hohzaki *et al.* [38]). The formulations (E_T) and (E_S) require order $O(K^2 T e_0)$ of memory size. From this fact, the formulations are preferable to (P_T) and (P_S) from the point of view of computational feasibility.

EXTENSIONS OF SAG

In this section, we consider the extension of our SAG model to more practical applications. First, we discuss the continuous SAG defined in continuous space. Further we mention other extensions or modifications of our models described in the sections titled "SAG for a Moving Target" and "Energy Constraints on Target Motion and Large-Size of Problems."

Continuous SAG and Applications

We replace the discrete search space in assumption (B1) with a continuous space $\mathbf{K} = [0, K] \subseteq \mathbf{R}$ and a continuous time $\mathbf{T} = [0, T] \subseteq \mathbf{R}$. We denote a distribution density of searching resource at point $(x, t) \in \mathbf{K} \times \mathbf{T}$ by $\varphi(x, t)$ and put a limit on the usage rate of the total available resource, $\int_{\mathbf{K}} \varphi(x, t) dx \leq \phi(t)$, at $t \in \mathbf{T}$. The target adopts a moving strategy denoted by a continuous and differentiable function of time $\omega(t) \in \mathbf{K}$, as in the discrete SAG. As the constraint on target motion, we replace condition (Eq. 4 with $|d\omega(t)/dt| \leq V_c$ and energy constraint (Eq. 5 with $\int_{\mathbf{T}} \mu(d\omega(t)/dt) dt \leq e_0$.

For the continuous SAG with payoff $R(\varphi, \omega) = 1 - \exp\{-\int_{\mathbf{T}} \alpha_{\omega(t)} \varphi(\omega(t), t) dt\}$ defined by strategies $\varphi(x, t)$ and $\omega(t)$, we have the following theorem about the relationship between a continuous SAG and the corresponding discrete SAG that is derived from the continuous SAG by discretizing the continuous space $\mathbf{K} \times \mathbf{T}$ in an appropriate manner. It is proved that a sequence of equilibrium points of the corresponding discrete SAGs converges to the equilibrium of the continuous SAG [39].

Theorem1 [39]. *There exists an equilibrium point for the continuous SAG and it is given by the convergence point for the corresponding discrete SAGs when the number of pieces the search space is divided into approaches infinity.*

When we divide a multidimensional continuous space into pieces such as $\mathbf{K} = \{1, \dots, n\}$ and construct a corresponding discrete SAG, we can compute an approximation close to an optimal strategies of the continuous SAG by the formulations in the sections titled “SAG for a Moving Target” and “Energy Constraints on Target Motion and Large-Size of Problems.” For a search game with a diffusively moving target on a plane, named a *flaming datum search game*, Washburn and Hohzaki [40,41] proposed some estimations of upper bound and lower bound for the value of the game by optimal control theory. They confirm that a sequence of optimal solutions of the corresponding

discrete games converges to an optimal one of the original continuous SAG by Theorem 1 and they numerically observe that the values of the discrete SAGs always stay between the lower and upper bounds of Washburn and Hohzaki.

We can demonstrate other practical applications of the SAG, taken in Hohzaki *et al.* [38], for which we can derive optimal solutions by the minor modification of the formulations (E_T) and (E_S) in the section titled “Energy Constraints on Target Motion and Large-Size of Problems.” The first example is a search game with shelter, which gives the target a safe place. The second one is about the good timing of the target’s energy supply or charging battery by a submarine in the ASW operation.

SAG with False Contacts

False contacts by sensors are inevitable in practical search operations, especially in the ASW. The event of false contacts has been an important theme in search theory. Stone discusses in a chapter of his book about his analysis of the event [8]. Sonar could pick up signals from false targets such as whales or from noises and sonar men could fail to recognize origins of signals correctly. Therefore, they inspect the first signals several times and grade up their correctness through the inspection process. Kisi [42] and Iida *et al.* [43] consider false contacts, which are assumed to occur according to the Poisson distribution, and discuss the inspection time to maximize the detection probability of true target within a limited amount of time. Their problem is a kind of one-sided optimization problem, in which the searcher determines the inspection time for a signal each time it occurs. When a false contact occurs, much inspection time increases the probability to recognize correctly what it is but makes the searcher spend time in vain without identifying true contacts. In Hohzaki [44], the author considers the following game, assuming that the probability of false-contact occurring depends on the amount of used resource or the number of dropped sonars.

In Hohzaki’s model, the following additional assumption (F1) about false contacts is added to the basic model of (B1)–(B5) in

the section titled “SAG for a Moving Target”: (F1). Given that the search is executed at time t , a false contact occurs with probability $q_t \equiv \sum_i \beta_i \varphi(i, t) + \gamma(t)$ at the end of time t . The coefficient β_i indicates the inducing efficiency of unit searching effort in cell i and $\gamma(t)$ is the stationary occurrence rate. Both parameters are positive and small enough to satisfy $\max_i \beta_i \Phi(t) + \gamma(t) < 1$. On the occurrence of a false contact, the searcher focuses on the investigation of the contact and he can start the search again after a fixed length of time period t_f at the earliest.

In the SAG with false contacts, the searcher cannot carry out search operations during the inspection process for false contacts. If the searcher distributes many resources aiming to detect the true target, his behavior increases the probability of false-contact occurrence as well as the detection probability of the target and it results in many time periods in which the searcher cannot search. The false-contact model requires the searcher to make an adequate distribution plan of searching resource while balancing the trade-off between the detection of target and the occurrence of false contacts.

If we denote the probability that the searcher can search at time $t \in \hat{\mathbf{T}}$ by $S(t)$, the probability satisfies the following recursive equations and then we can evaluate the payoff of a searcher's strategy φ and a target's path ω by $R(\varphi, \omega) = \sum_{t=\tau}^T S(t) \alpha_{\omega(t)} \varphi(\omega(t), t)$.

$$S(t) = \begin{cases} 1, & \text{for } t = \tau \\ S(t-1)(1 - q_{t-1}), & \text{for } \tau + 1 \leq t \leq \tau + t_f - 1 \\ S(t-1)(1 - q_{t-1}) + S(t-t_f)q_{t-t_f}, & \text{for } \tau + t_f \leq t \leq T. \end{cases}$$

The equations above implicitly involve the searcher strategy φ in a complicated manner and then the payoff does so. In spite of the nonlinearity, we can propose a linear programming problem for the optimal strategies by means of transformation and substitution (see Hohzaki [44]). In the ASW, contact information is classified into several grades based on its correctness. The false-contact model is extended to the model with several types of false contacts by Hohzaki [45].

Other Applications

In this section, we show some other applications of the SAG.

SAG Taking Account Of Attributes Of Searching Resource. We use many kinds of searching resources in search operations, for example, sonar buoys for submarines, searching time or manpower for the search. Taking an example of a flare used in search-and-rescue operations, its effect lasts for some time and extends to some areas at a distance from its shooting point. Hohzaki [46,47] embedded the durability and reachability of searching resources in his SAG model. Dambreville and Le Cadre [48,49] considered a variety of constraints on the amount of resource. To the basic SAG model (B1)–(B5), Hohzaki introduced an additional assumption: (P1). The effect of the resource lasts for time duration D after its dropped time. Furthermore, it expands to an area $A(i) \subseteq \mathbf{K}$ although the intensity of the effect attenuates by $\beta(i, j)$ based on the distance from the dropped point i to a point j .

The payoff of the SAG model is

$$R(\varphi, \omega) = \sum_{t \in \hat{\mathbf{T}}} \alpha_{\omega(t)} \sum_{\xi = \max\{\tau, t-D\}}^t \sum_{j \in A^*(i)} \beta(j, \omega(t)) \varphi(j, \xi),$$

where $A^*(i)$ is the set of cells at which the resource dropped has effects on cell i and is defined by $A^*(i) \equiv \{j \in \mathbf{K} | i \in A(j)\}$.

SAG with Energy Supply Strategy. Apart from submarines or other vehicles, energy is crucial to the mobility of the target and the mobility gives the target the flexibility to avoid searchers in search games. The submarine supplies his energy at the risk of letting himself more likely to be detected by the searcher. Some articles deal with the strategy of energy supply as a target strategy. In Hohzaki and Ikeda [50], they put an extra assumption to the basic SAG model: (S1). A target can supply his energy by $\delta > 0$ during a time period. As well as the selection of his paths, he chooses one of the two options concerning the supply of energy: supply or no

supply. If he takes the strategy of supply, his energy increases by δ at the end of a relevant time point or at the beginning of the next time. But, during the supply, the effectiveness of unit searching resource in cell i on target detection changes from α_i to β_i , where $\alpha_i < \beta_i$ usually holds.

In this model, a target pure strategy is denoted by a combination of a path $\omega \in \Omega$ and a supply rule $\sigma = \{\sigma(t), t \in \mathbf{T}\}$, where $\sigma(t)$ is 1 for “Supply” and 0 for “No-supply” at time t . For a searcher strategy φ and a target strategy $\rho = (\omega, \sigma)$, the payoff of the SAG with energy supply strategy is given by

$$R(\varphi, \rho) = \sum_{t \in \mathbf{T}} \varphi(\omega(t), t) \{ \alpha_{\omega(t)} [1 - \sigma(t)] + \beta_{\omega(t)} \sigma(t) \}.$$

Miscellanea. There are other topics concerned with the SAG. We mentioned a datum search game on a two-dimensional space in the section titled “Continuous SAG and Applications.” The ASW forces sometimes repeat contact and loss of submarine’s signals in the real ASW. Therefore, we are also interested in the result that the target and the searcher fight each other in a sequence of such datum search games. The game could be modeled by a multi-stage SAG. At each stage when an element datum search game is played, the submarine loses some of his energy but gets information about searching resource of the searcher, and the searcher obtains some information about whereabouts of the target while consuming searching resource. In the multi-stage SAG, players have to make a sequence of decisions, for example, “where should I go next?” or “how much resource and where I’d better distribute?”. Hohzaki [51] analyzed the multi-stage SAG.

The SAG implicitly presumes the competition between a searcher and a target in the ASW operation. That is why almost all research on the SAG was modeled by noncooperative two-person zero-sum game. However, if there are multiple searchers involved in the SAG such as treasure hunting, each searcher would compete with others to get the value of target. In such an SAG, each searcher would behave to increase his own

interest and the payoff of the game would be nonzero-sum. Hohzaki [52] discussed a nonzero-sum search game with two competitive searchers and a target, and he showed that there is certainly an equilibrium point, in which both searchers cooperatively act as a team to get reward by detection of target if the target is stationary. In such an equilibrium, the nonzero-sum SAG with multiple searchers and a stationary target is essentially the same as a two-person zero-sum SAG with a team of searchers and a target as two competitors. Whether this property is valid for a moving target SAG is still an open problem.

For the SAG, the assumption of noncooperativeness has been kept for a long time. However we can imagine some situations in which some players might take a cooperative operation. Several searchers could help each other to search for a target. For example, some players or some companies organize a syndicate to search for valuable minerals. Coast guard or navy could take a cooperative operation to search for missing persons at sea. Hohzaki [53] discussed a cooperative SAG, where some searchers cooperate against a target. He first derives the conditions that give searchers an incentive to form a coalition and then models the SAG by the so-called coalition game of cooperative game (see Owen [37]). He generates characteristic functions customized to search operations and proposes a methodology to divide the obtained target value among members of the coalition. The cooperative SAG has just started and there is much future work to be done to clarify the properties of the cooperative SAG.

Physics, Charles University in
Prague, Czech Republic

PRELIMINARIES

Recall that basic data specifying a cooperative game with TU, that is transferable utility (or with side payments), in short a TU game or a game, are composed of a nonempty set N and a real-valued function v defined on the collection of all subsets of N and having the property $v(\emptyset) = 0$ where $\emptyset$ stands for the empty set. We shall denote the game given through N and v by (N, v) , or simply v , and the collection of all TU games with player set N by $\mathcal{G}(N)$. As usual, the elements of N are called *players*, subsets of N (inclusive of the empty set and entire set N) are called *coalitions*, the set N of all players is referred to as the *grand coalition*, and the function v is called the *characteristic function* of the game or *coalition function*. If S and T are coalitions such that $S \subset T$, then we say that S is a *sub-coalition* of T and T is a *supercoalition* of S .

It is customary to interpret the value $v(S)$ of characteristic function v at coalition S as the worth of coalition S or the total payoff that coalition S will be able to distribute among its members, provided exactly the coalition S forms. However, equally well, the number $v(S)$ may represent the total cost of reaching some common goal of coalition S that must be shared by the members of S ; or some other quantity, depending on the application field.

Note that the sum $v + w$ of games from $\mathcal{G}(N)$ defined by $(v + w)(S) = v(S) + w(S)$ is again a game from $\mathcal{G}(N)$. Moreover, if multiplication of $v \in \mathcal{G}(N)$ by a real number α is defined by $(\alpha v)(S) = \alpha v(S)$, then αv also belongs to $\mathcal{G}(N)$. An important and well-known fact is that $\mathcal{G}(N)$ endowed with these

two algebraic operations is a real linear space.

Occasionally, we also need games whose set of players is different from N . In particular, for every game v from $\mathcal{G}(N)$ and every subset S of N , the *subgame* of v is the game $(S, v|_S)$ with player set S whose characteristic function $v|_S$ is defined by $v|_S(Q) = v(Q)$ for every subset Q of S .

We shall be concerned with the class of TU games in which the number of players is finite. For simplicity of notation, if the number of players is n , then we identify (name) the players with the first natural numbers $1, 2, \dots, n$. Accordingly, the grand coalition N is the set $\{1, 2, \dots, n\}$, the coalitions are subsets of $\{1, 2, \dots, n\}$, and the characteristic function v assigns to every subset S of $\{1, 2, \dots, n\}$ a real number $v(S)$.

SOLUTION FUNCTIONS

There is a variety of solution concepts for TU games. Some, like the cores or stable sets, consist of sets of real n -vectors, while others offer as a solution of a game, a single real n -vector. We restrict attention to the latter concept; that is, we are interested in a mapping $f = (f_1, f_2, \dots, f_n)$ that assigns to every game v from some collection of games in $\mathcal{G}(N)$ a real n -vector $f(v) = (f_1(v), f_2(v), \dots, f_n(v))$ and satisfies some prescribed desirable properties. Following the basic interpretation of values of characteristic functions as payoffs, we can interpret the values of components of such a solution function as payoffs to individual players in game v .

Definition 1. Let $\mathcal{A}$ be a nonempty collection of games from $\mathcal{G}(N)$. A *solution function on $\mathcal{A}$* is a mapping f from $\mathcal{A}$ into the n -dimensional real linear space $\mathcal{R}^n$. If the domain of f is not explicitly specified, then it is assumed to be $\mathcal{G}(N)$.

The collection of such mappings is too broad to contain only the mappings that lead to sensible solution concepts. Hence, to obtain

reasonable solution concepts we have to require that the solution functions have some reasonable properties. One of the natural properties in many contexts is the following property of efficiency.

Property 1 [Efficiency]. A solution function f on a subset $\mathcal{A}$ of $\mathcal{G}(N)$ is *efficient on $\mathcal{A}$* if

$$f_1(v) + f_2(v) + \cdots + f_n(v) = v(N) \quad (1)$$

for every game v from $\mathcal{A}$.

This property can be interpreted as a combination of the requirements of the *feasibility*

$$f_1(v) + f_2(v) + \cdots + f_n(v) \leq v(N)$$

and *collective rationality*

$$f_1(v) + f_2(v) + \cdots + f_n(v) \geq v(N).$$

Note that the efficiency demands that the grand coalition forms and distributes the total payoff $v(N)$ among all its players. This is a natural requirement in many situations. Nevertheless, we should keep in mind that occasionally, forming the grand coalition may not be efficient in an economic sense. For example, in some games there may be one or more subcoalitions of the grand coalition that have strictly greater worth than the grand coalition has.

In addition to satisfying the efficiency condition, solution functions are required to satisfy a number of other desirable properties. To introduce some of them, we need further definitions.

Player i from N is a *null player* in game v if

$$v(S \cup \{i\}) = v(S) \quad (2)$$

for every coalition S that does not contain player i ; that is, participation of a null player in a coalition does not contribute anything to the coalition in question.

Player i from N is a *dummy player* in game v if

$$v(S \cup \{i\}) = v(S) + v(\{i\}) \quad (3)$$

for every coalition S that does not contain player i ; that is, a dummy player contributes to every coalition the same amount, his or her value of the characteristic function.

Players i and j from N are *interchangeable* in game v if

$$v(S \cup \{i\}) = v(S \cup \{j\}) \quad (4)$$

for every coalition S that contains neither player i nor player j . In other words, two players are interchangeable if they can replace each other in every coalition that contains one of them.

Property 2 [Null player]. A solution function f satisfies the *null player property* if $f_i(v) = 0$ whenever $v \in \mathcal{G}(N)$ and i is a null player in v .

Property 3 [Dummy player]. A solution function f satisfies the *dummy player property* if $f_i(v) = v(\{i\})$ whenever $v \in \mathcal{G}(N)$ and i is a dummy player in v .

Property 4 [Equal treatment]. A solution function f satisfies the *equal treatment property* if $f_i(v) = f_j(v)$ for every $v \in \mathcal{G}(N)$ and every pair of players i, j that are interchangeable in v .

Properties (2)–(4) are quite reasonable, especially with regard to fairness and impartiality: a player who contributes nothing should get nothing; a player who contributes the same amount to every coalition cannot expect to get anything more than what he or she contributed; and two players who contribute the same to each coalition should be treated equally by the solution function.

The next property reflects the natural requirement that the solution function should be independent of the players' names. Let v be a game from $\mathcal{G}(N)$ and $\pi: N \rightarrow N$ be a permutation of N , and let the image of coalition S under π be denoted by $\pi(S)$. It is obvious that, for every $v \in \mathcal{G}(N)$, the function πv defined on $\mathcal{G}(N)$ by

$$(\pi v)(S) = v(\pi(S))$$

is again a game from $\mathcal{G}(N)$. Apparently, the game πv differs from game v only in players' names; they are interchanged by the permutation π .

Property 5 [Anonymity]. A solution function f is said to be *anonymous* if, for every permutation π of N ,

$$f_i(\pi v) = f_{\pi(i)}(v)$$

for every game $v \in \mathcal{G}(N)$ and every player $i \in N$.

Property 6 [Additivity]. A solution function f on $\mathcal{G}(N)$ is said to be *additive* if

$$f(u + v) = f(u) + f(v),$$

for every pair of games u and v from $\mathcal{G}(N)$.

It is natural for solution functions to be additive when a game consists of two independent games played separately by the same players or if a game is split into a sum of games. However, observe that the requirement of additivity differs from the other conditions in one important aspect. It involves two different games that may or may not be mutually dependent. In contrast, the dummy player and equal treatment properties involve only one game, and the anonymity property involves only games completely determined by a single game.

On some occasions, we need the properties to be valid only on a subset $\mathcal{A}$ of $\mathcal{G}(N)$. Then, when necessary, we require that πv , or $u + v$, belong to $\mathcal{A}$ whenever v , or u and v , are in $\mathcal{A}$.

Remark 1. The terminology introduced in the literature for various properties of players and solution functions is not completely standardized. For example, some authors use the term “dummy player” and “symmetric players” (or “substitutes”), for what we call null player and interchangeable players, respectively. Moreover, the term “symmetry” is sometimes used for our equal treatment and sometimes for our anonymity.

SHAPLEY VALUE

The Shapley solution function or briefly the Shapley value, proposed by Shapley [1] in 1953, is undoubtedly one of the most studied and most influential solution concepts for TU games. In addition to its theoretical significance, the Shapley value has a remarkably wide range of applications, particularly in economic and political models. Therefore, it is not surprising that there are several ways to introduce the Shapley value.

Basic Framework

Perhaps the simplest way of introducing the Shapley value is to define it explicitly by the following well-known formula for calculation of its components.

Definition 2. The Shapley value on a subset $\mathcal{A}$ of $\mathcal{G}(N)$ is a solution function φ on $\mathcal{A}$ whose components $\varphi_1(v), \varphi_2(v), \dots, \varphi_n(v)$ at game $v \in \mathcal{A}$ are defined by

$$\varphi_i(v) = \sum_{S: i \in S} \frac{(s-1)!(n-s)!}{n!} [v(S) - v(S \setminus \{i\})], \quad (5)$$

where the sum is meant over all coalitions S containing player i and s generically stands for the number of players in coalition S .

It can easily be seen that the components of the Shapley value can be computed also by the formula

$$\varphi_i(v) = \sum_{S: i \notin S} \frac{s!(n-s-1)!}{n!} [v(S \cup \{i\}) - v(S)], \quad (6)$$

where the sum is meant over all coalitions S not containing player i .

To clarify the basic idea behind this definition we first recall the notion of players' marginal contributions to coalitions.

Definition 3. For each player i and each coalition S , a *marginal contribution* of player i to coalition S in game v from $\mathcal{G}(N)$ is the number $m_i^v(S)$ defined by

$$m_i^v(S) = \begin{cases} v(S) - v(S \setminus \{i\}), & \text{if } i \in S; \\ v(S \cup \{i\}) - v(S), & \text{if } i \notin S. \end{cases}$$

Now imagine a procedure for dividing the total payoff $v(N)$ among the members of N , in which the players enter a room in some prescribed order and each player receives as payoff his or her marginal contribution to the coalition of players already in the room. Suppose that the prescribed order is $(\pi(1), \pi(2), \dots, \pi(n))$ where $\pi: N \rightarrow N$ is a fixed permutation of N . Then the procedure under consideration determines the payoffs to individual players as follows: Before the first player $\pi(1)$ entered the room, there was the empty coalition waiting in the room. And after player $\pi(1)$ enters, the coalition in the room becomes $\{\pi(1)\}$ and the player receives $v(\{\pi(1)\}) - v(\emptyset)$. Similarly, before the second player $\pi(2)$ entered, there was coalition $\{\pi(1)\}$ waiting in the room. After player $\pi(2)$ enters, coalition $\{\pi(1), \pi(2)\}$ is formed in the room and player $\pi(2)$ receives $v(\{\pi(1), \pi(2)\}) - v(\{\pi(1)\})$. This continues till the last player $\pi(n)$ enters and receives $v(N) - v(N \setminus \{\pi(n)\})$.

Let S_i^π denote the coalition of players preceding player i in the order $(\pi(1), \pi(2), \dots, \pi(n))$; that is, $S_i^\pi = \{\pi(1), \pi(2), \dots, \pi(j-1)\}$ where j is the uniquely determined member of N such that $i = \pi(j)$. Because there are $n!$ possible orders, the arithmetic average of the marginal contributions of player i taken over all possible orderings is equal to the number $(1/n!) \sum_\pi m_i^v(S_i^\pi)$, where the sum is understood over all permutations π of N . It can easily be verified by simple computation that this number is exactly the i th component of the Shapley value. Therefore, in addition to the equality of formulas (5) and (6), we also have the formula

$$\varphi_i(v) = \frac{1}{n!} \sum_\pi m_i^v(S_i^\pi) \quad (7)$$

for computing the components of the Shapley value.

If all orders of arrival of players are equally probable, then the probability that player i arrives after the players of S_i^π have already arrived and before the remaining players come, is equal to the number of possible orders of the form: first players in S_i^π (in some order), then player i , and then players in $N \setminus (S_i^\pi \cup \{i\})$ (in some order) divided by

the total number of possible orders of players in N . And this is equal to $(s-1)!(n-s)!/n!$ where s is the number of players in coalition $S = S_i^\pi \cup \{i\}$. Consequently, we conclude that the i th component of the Shapley value can be interpreted as the expected payoff to player i under this randomization scheme.

We have seen that the marginal contributions of players with respect to the order given by a fixed permutation π are given by

$$\begin{aligned} m_1^v(S_1^\pi) &= v(\{\pi(1)\}) - v(\emptyset), \\ m_2^v(S_2^\pi) &= v(\{\pi(1), \pi(2)\}) - v(\{\pi(1)\}), \\ &\vdots \\ m_n^v(S_n^\pi) &= v(\{\pi(1), \pi(2), \dots, \pi(n)\}) \\ &\quad - v(\{\pi(1), \pi(2), \dots, \pi(n-1)\}). \end{aligned}$$

It is clear that the sum of these contributions equals $v(N)$. It follows that the sum of the arithmetic averages of players' marginal contributions taken over all possible orderings must also add up to $v(N)$. Hence, the Shapley value satisfies the requirement of efficiency.

In addition to satisfying the condition of efficiency, the Shapley value has a number of other useful properties. In particular, it satisfies all of properties 2–6. Remarkably, no other solution function on $\mathcal{G}(N)$ satisfies the properties of null player, equal treatment, and additivity at the same time.

Theorem 1 [Shapley]. *For each N , there exists a unique solution functions on $\mathcal{G}(N)$ satisfying the properties of efficiency, null player, equal treatment, and additivity; this solution function is the Shapley value introduced by Definition 2.*

The standard proof of this basic result follows from the following facts:

- The collection $\{u_T : T \neq \emptyset, T \subset N\}$ of unanimity games defined by

$$u_T(S) = \begin{cases} 1, & \text{if } T \subset S; \\ 0 & \text{otherwise,} \end{cases} \quad (8)$$

form a base of the linear space $\mathcal{G}(N)$.

- The null player and equal treatment properties guarantee that φ is determined uniquely on multiples of unanimity games.
- The property of additivity (combined with the fact that the unanimity games form a basis) makes it possible to extend φ in a unique way to the whole space $\mathcal{G}(N)$.

Alternative Characterizations

One of the most useful aspects of the Shapley value is that it can be characterized by different sets of properties. For example, an easy modification of the previous theorem can be obtained by replacing the properties of null player and equal treatment by those of dummy player and anonymity.

The formulas (5)–(7) suggest that the Shapley value of a given player at a given game depends only on the vector of his or her marginal contributions in the game under consideration. This is useful in applications because in practice only one problem at a time, represented by some specific game, is usually considered. However, unlike the efficiency, equal treatment, and null player properties, the requirement of additivity involves different games that may or may not be mutually unrelated. This, at least partly, can explain why a considerable portion of research effort in finding alternative characterizations has been focused on the possibility of eliminating the condition of additivity.

The efficiency, equal treatment, and null player property are sufficient to determine the Shapley value uniquely for some games but, in general, they are not sufficient to determine the Shapley value on $\mathcal{G}(N)$. Therefore, just omitting the condition of additivity will not help.

Monotonicity and Marginality. Young [2] introduced the following monotonicity property for solution functions that makes it possible to characterize the Shapley value without using the condition of additivity.

Property 7 [Strong monotonicity]. A solution function f is said to be *strongly monotone* if, for every player i , $f_i(u) \geq f_i(v)$

whenever $m_i^u(S) \geq m_i^v(S)$ for every coalition S .

Theorem 2 [Young]. *For each N , the Shapley value is the only solution function on $\mathcal{G}(N)$ satisfying efficiency, strong monotonicity, and equal treatment.*

Moreover, Young [3] also showed that the Shapley value is the unique anonymous efficient solution function that satisfies the following marginality principle.

Property 8 [Marginality principle]. A solution function f is said to satisfy the *marginality principle* if $m_i^u = m_i^v$ implies $f_i(u) = f_i(v)$ for every player i and every two games u and v from $\mathcal{G}(N)$.

Potential. Both of Young's characterizations of the Shapley value also involve the characteristic functions of different, possibly independent games. The following approach proposed by Hart and Mas-Colell [4] shows that it is possible to characterize the Shapley value of a game by conditions involving only games determined by the values of the characteristic functions of the game itself.

To describe these results we first recall that for each game v from $\mathcal{G}(N)$, the functions $v|_S$ defined on the collection of all subcoalitions Q of coalition S by $v|_S(Q) = v(Q)$ are called subgames of game v . Let G_v denote the set of all subgames of game v and let p be a real-valued function on G_v . We introduce the notions of players' marginal contributions according to p , and of a potential function on G_v as follows.

Definition 4. The *marginal contribution* of a player i from a coalition S according to a function p on G_v is the difference $D_i^p(S) = p(v|_S) - p(v|_{S \setminus \{i\}})$. If p is such that $p(v|_\emptyset) = 0$ and $\sum_{i \in N} D_i^p(N) = v(N)$, then p is called a *potential function*.

Theorem 3 [Hart and Mas-Colell]. *For every game v in $\mathcal{G}(N)$, there exists a unique*

potential function p on G_v , and the resulting vector

$$(D_1^p(N), D_2^p(N), \dots, D_n^p(N))$$

of players' marginal contributions according to p coincides with the Shapley value of game v .

Because the potential of every game is determined only by the game and its subgames, we have another characterization of the Shapley value without requiring additivity. Moreover, the equality $D_i^p(N) = \varphi_i(v)$ provides an alternative way for computing the components of the Shapley value. Indeed, by rewriting the efficiency condition $\sum_{i \in N} D_i^p(N) = v(N)$ into

$$p(v|_N) = \frac{1}{n} \left(v(N) + \sum_{i \in N} p(v|_{N \setminus \{i\}}) \right), \quad (9)$$

and starting with the initial condition $p(v|_\emptyset) = 0$, we obtain a recursive way for computing the values of the potential function appearing in the definition of $D_i^p(N)$, $i = 1, 2, \dots, n$.

SHAPLEY VALUE FOR SUBCLASSES

Originally, Shapley did not consider explicitly the linear space $\mathcal{G}(N)$ of all games with a fixed finite set of players but the collection of superadditive games with an arbitrary finite number of players taken from a potentially infinite set of players, where the *superadditivity* of a game v means that the inequality $v(S) + v(T) \leq v(S \cup T)$ is satisfied for every pair of disjoint coalitions S and T .

The sum of two superadditive games is again a superadditive game and a multiple of a superadditive game by a nonnegative number is also a superadditive game; in other words, the set of superadditive games from $\mathcal{G}(N)$ forms a cone in $\mathcal{G}(N)$. Because the superadditive games belong to $\mathcal{G}(N)$, it is evident that the properties that characterize the Shapley value on $\mathcal{G}(N)$ are also satisfied by superadditive games, provided that the property under consideration is applicable under the assumption of superadditivity.

Less obvious (but easily verifiable) is the fact that these properties also guarantee the uniqueness of the Shapley value on the cone of superadditive games in $\mathcal{G}(N)$. Because various special classes of games occur in practice, it is of interest to identify other subclasses of games from $\mathcal{G}(N)$ on which the Shapley value can be characterized by the same or similar properties as in the case of $\mathcal{G}(N)$.

Additive Groups of Games

Neyman [5] demonstrated that a characterization of the Shapley value by the properties of efficiency, null player, equal treatment, and additivity is possible on the set of linear combinations with integer-valued coefficients of games determined by a fixed game from $\mathcal{G}(N)$.

For a game v from $\mathcal{G}(N)$, let $\mathcal{A}_v$ be the collection of all games from $\mathcal{G}(N)$ defined by the condition that $w \in \mathcal{A}_v$ if and only if there are a positive integer m , integers (not necessarily positive) $\alpha_1, \alpha_2, \dots, \alpha_m$ and coalitions $S_1, S_2, \dots, S_m$ such that

$$w = \sum_{k=1}^m \alpha_k v_{S_k},$$

where, for each k , the game v_{S_k} is defined by $v_{S_k}(T) = v(S_k \cap T)$, $T \subset N$.

Theorem 4 [Neyman]. *If f is a solution function on $\mathcal{A}_v$ satisfying efficiency, additivity, equal treatment, and the null player property, then it is the Shapley value on $\mathcal{A}_v$.*

Theorem 5 [Neyman]. *If f is a solution function on $\mathcal{A}_v$ satisfying efficiency, strong monotonicity, and the equal treatment property, then it is the Shapley value on $\mathcal{A}_v$.*

Simple Games

The set of games from $\mathcal{G}(N)$ whose characteristic functions assume only values 0 or 1, and some of its subsets, appear naturally in everyday life. Such games can be viewed as models of yes–no voting systems; that is, systems whose rules specify which collections of

“yes” votes guarantee passage of the issue at hand. In conformity with this interpretation, a set S of voters is said to be a *winning* coalition if passage of the issue is guaranteed by “yes” votes from S . Naturally, coalitions that are not winning are called *losing* coalitions. The corresponding voting game v is then defined by setting $v(S) = 1$ if S is winning, and $v(S) = 0$ if S is losing. We refer to such cooperative games as *simple* games. The solution functions defined on the set (or on some specific subsets) of simple games are often called *indices of power*; see the article titled **Power Indices**.

Remark 2. In this generality, a simple game can be considered as a pair (N, W) where W is a given collection of coalitions called winning coalitions. Such objects are often called hypergraphs. To distinguish the simple games from hypergraphs, many authors exclude some games from what we call simple games. For example, Taylor and Zwicker [6] reserve the term “simple game” for a simple game that is monotone in the sense that every supercoalition of a winning coalition is also winning. Sometimes, only the identically zero game is excluded; sometimes it is required that the grand coalition is winning and all singleton coalitions are losing.

In contrast to the case of superadditive games, the sum of two simple games need not be a simple game. Therefore, it is immediate that the requirement of additivity needs modification. One possibility is to require additivity only for those pairs of simple games whose sum is also a simple game. Dubey [7] showed that this modification is sufficient for proving the uniqueness of Shapley’s value on the class of all simple games.

The situation is different when we consider not identically zero monotonic simple games. First we observe that, in monotonic simple games, the players’ marginal contributions also assume only the values from the set $\{0, 1\}$. Specifically, $m_i^v(S) = 1$ only in two cases: either S is losing and $S \cup \{i\}$ is winning, or S is winning and $S \setminus \{i\}$ is losing. It follows that the formulas (5)–(7) can be simplified. For example, formula (5) can be simplified to

$$\varphi_i(v) = \sum \frac{(s-1)!(n-s)!}{n!}, \quad (10)$$

where the sum is meant over all winning coalitions S containing player i and such that coalition S_i and all its subcoalitions are losing.

It follows from the monotonicity that for every permutation π , there is exactly one player such that the coalition S_i^π of players preceding player i in the order given by π is losing and the coalition $S_i^\pi \cup \{i\}$ is winning. We say that this player is *pivotal* for π . Recalling the room example with orders of equal probability, we can easily see that Equation (10) can be expressed in the form

$$\varphi_i(v) = \frac{\text{the number of permutations for which } i \text{ is pivotal}}{\text{the number of all permutations}}. \quad (11)$$

As a rule, this specification of the Shapley value to the case of monotonic simple games is called the *Shapley Shubik power index*.

In contrast to the general case, the null player and equal treatment properties, together with efficiency and the mentioned modification of additivity, do not guarantee uniqueness of the Shapley value on the set of monotonic simple games. To deal with this situation, Dubey proposed replacing additivity of the solution function by its modularity.

To present this modification, we first notice that for every pair of monotonic simple games u and v , the games $\max(u, v)$ and $\min(u, v)$ defined by

$$\max(u, v)(S) = \max\{u(S), v(S)\},$$

$$\min(u, v)(S) = \min\{u(S), v(S)\},$$

are also monotonic simple games. It is easily seen that a coalition is winning in game $\max(u, v)$ if it is winning in game u or game v , and it is winning in game $\min(u, v)$ if it is winning in both u and v . Thus, a coalition wins in games u and v as often as in games $\max(u, v)$ and $\min(u, v)$.

Property 9 [Modularity]. A solution function f on the set of simple games is *modular*

if

$$f(u) + f(v) = f(\max(u, v)) + f(\min(u, v)),$$

for every pair of simple games u and v .

Theorem 6 [Dubey]. *The Shapley Shubik index is a unique solution function on the class of monotonic simple games that is efficient and has the dummy player, anonymity, and modularity properties.*

SOLUTIONS WITH COOPERATION STRUCTURES

The class of simple games considered in the previous section arises by restricting the range of characteristic functions. On the other hand, there are situations in which it may be reasonable to relax the condition (tacitly assumed in the efficiency requirement) that only the grand coalition forms. As examples we can take the formation of cartels, trading blocs, political parties or various joint ventures. Such relaxations are usually modeled by adjoining to a game some structure on the set of coalitions. We shall call such structures *cooperation structures*. From the wide variety of such structures appearing in the literature, we consider only the structures given by the requirement that each player belongs exactly to one coalition, and the structures given by graphs on the set of players.

Aumann Drèze Value

We begin with the cooperation structures given by partitions of the grand coalition.

Definition 5. A *coalition structure* is a partition of the grand coalition; that is, a collection of pairwise disjoint nonempty coalitions whose union is the grand coalition.

Probably the first extension of the Shapley value to games with a coalition structure was proposed by Aumann and Drèze [8] who analyzed the idea that, for a game v and a coalition structure $\mathcal{C}$, the payoff to player i should be the Shapley value of player i in the game restricted to subcoalitions of the

coalition that contains player i and belongs to partition $\mathcal{C}$.

Let such a payoff to player i be denoted by $\Phi_i(v, \mathcal{C})$. Then, this suggestion requires that

$$\Phi_i(v, \mathcal{C}) = \varphi_i(v, S),$$

where coalition S is a member of partition $\mathcal{C}$, player i belongs to S , and $\varphi_i(v, S)$ is defined by

$$\begin{aligned} \varphi_i(v, S) = \sum_{T \subset S \setminus \{i\}} \frac{t!(s-t-1)!}{s!} \\ \times [v(T \cup \{i\}) - v(T)]. \end{aligned} \quad (12)$$

It is worth noticing that $\Phi_i(v, \mathcal{C})$ reduces to the ordinary Shapley value of player i when $\mathcal{C}$ is the trivial partition $\{N\}$ and that, in general, the sum $\sum_{i=1}^n \Phi_i(v, \mathcal{C})$ may be different from $v(N)$. Thus $\Phi = (\Phi_1, \dots, \Phi_n)$ is not necessarily efficient. However, it is evident that the following property of relative efficiency is satisfied.

Property 10 [Relative efficiency]. If $\mathcal{C} = \{C_1, \dots, C_m\}$ is a coalition structure for N and v is a game from $G(N)$, then

$$\sum_{j \in C_k} \Phi_j(v, \mathcal{C}) = v(C_k),$$

for every $1 \leq k \leq m$.

Definition 6. Let $\Pi(N)$ be the collection of all partitions of N and let $\mathcal{B}$ be a subset of $\Pi(N)$. A *coalitional solution function* on a subset $\mathcal{A}$ of $\mathcal{G}(N)$ with a coalition structure from $\mathcal{B}$ is a mapping $f = (f_1, f_2, \dots, f_n)$ from the Cartesian product $\mathcal{A} \times \mathcal{B}$ into n -dimensional real linear space $\mathcal{R}^n$.

Aumann and Drèze showed that $\Phi = (\Phi_1, \Phi_2, \dots, \Phi_n)$ defined by formula (12) is the unique relatively efficient coalitional solution function on $\mathcal{G}(N) \times \Pi(N)$ that satisfies the following natural extensions of the null player, anonymity, and additivity properties.

- **Null Player:** If i is a null player, then $f_i(v, \mathcal{C}) = 0$ for every pair $v \in \mathcal{G}(N)$ and $\mathcal{C} \in \Pi(N)$.

- *Anonymity*: For every permutation π on N and every coalition structure $\mathcal{C} = \{C_1, \dots, C_m\}$ from $\Pi(N)$, we have $f(\pi v, \pi \mathcal{C}) = \pi f(v, \mathcal{C})$ where $\pi \mathcal{C} = \{\pi(C_1), \pi(C_2), \dots, \pi(C_m)\}$ and $\mathcal{C}$ is invariant under π in the sense that $\pi(C_k) = C_k$ for all $1 \leq k \leq m$.
- *Additivity*: If u and v are games from $\mathcal{G}(N)$, then $f(u + v, \mathcal{C}) = f(u, \mathcal{C}) + f(v, \mathcal{C})$ for every coalition structure $\mathcal{C} \in \Pi(N)$.

Moreover, Myerson [9] proved that the Aumann–Dr ze generalization of the Shapley value is the unique relatively efficient coalitional solution function satisfying the condition:

$$\varphi_i(v, S) - \varphi_i(v, S \setminus \{j\}) = \varphi_j(v, S) - \varphi_j(v, S \setminus \{i\}), \quad (13)$$

for all i and j in S .

Owen Value

A different extension of the Shapley value to games with coalition structures was introduced by Owen [10]. As in the Shapley value, players get their expected marginal contributions with respect to random orders of players, but the orders are required to be consistent with the coalition structure.

For a given coalition structure $\mathcal{C} = \{C_1, \dots, C_m\}$, let $\Omega_{\mathcal{C}}$ be the set of permutations π on N that are consistent with $\mathcal{C}$ in the sense that if $C_k \in \mathcal{C}$, $i, j \in C_k$, and $\pi(i) \leq \pi(l) \leq \pi(j)$, then l is in C_k .

Definition 7. The *Owen value* of player i in game v with coalition structure $\mathcal{C}$ is defined by

$$\phi_i(v, \mathcal{C}) = \frac{1}{\omega} \sum_{\pi \in \Omega_{\mathcal{C}}} [v(C_i^{\pi} \cup \{i\}) - v(C_i^{\pi})], \quad (14)$$

where ω is the number of permutations in $\Omega_{\mathcal{C}}$.

Notice that the Owen value is an efficient coalitional solution function; that is, $\sum_{i=1}^n \phi_i(v, \mathcal{C}) = v(N)$ for every v and $\mathcal{C}$. Also notice that the Owen value is equal to the Shapley value when $\mathcal{C} = \{\{1\}, \{2\}, \dots, \{n\}\}$.

Like the Shapley value, the Owen value can be characterized in several ways. For example, the Owen value is the only efficient coalitional solution function on $\mathcal{G}(N) \times \Pi(N)$ that is additive, has the null player property, and satisfies the following two symmetry requirements: For a game v and a coalition structure $\mathcal{C} = \{C_1, \dots, C_m\}$, we first define a “quotient” game $v_{\mathcal{C}}$ whose players are the coalitions in the original game v that are members of the partition $\mathcal{C}$. Formally, we take as the set of players the set $M = \{1, 2, \dots, m\}$ and define $v_{\mathcal{C}}$ by

$$v_{\mathcal{C}}(T) = v(\cup_{k \in T} C_k) \text{ for every } T \subset M.$$

Then, the mentioned symmetry requirements are defined in the following way.

- *Symmetry across Coalitions*: If players k and l in game $v_{\mathcal{C}}$ are symmetric in $v_{\mathcal{C}}$, then the total payoff to coalition C_k is the same as the total payoff to coalition C_l .
- *Symmetry within Coalitions*: For any two players i and j who are symmetric in game v and belong to the same member of coalition structure $\mathcal{C}$, the values of i and j are equal.

Recently, Khmelnitskaya and Yanovskaya [11] characterized the Owen value without using additivity. Namely, they showed that the additivity and null player properties in the characterization presented above can be replaced by the marginality principle.

Myerson Value

The third extension of the Shapley value to games with a cooperation structure is that proposed by Myerson [12] for a cooperation structure given by an undirected simple (that is, without self-loops and parallel edges) graph on the set of players. The edges of such a *cooperation graph* are often interpreted as communication channels between those players that can directly negotiate with each other, but various other interpretations are possible.

Let E be a cooperation graph. We say that players i and j are connected in coalition S

by E if there is a path in E between i and j that stays in S . Let S/E denote the partition of S into the collections of players that are connected in S by E , and define a game v^E by $v^E(S) = \sum_{T \in S/E} v(T)$.

Myerson established that the function $\phi^E = (\phi_1^E, \phi_2^E, \dots, \phi_n^E)$ defined by $\phi_i^E(v) = \varphi_i(v^E)$ (where φ denotes the ordinary Shapley value) is the only solution function satisfying the following two conditions:

- If S is a connected component of a cooperation graph E , then

$$\sum_{i \in S} \phi_i^E(v) = v(S).$$

- If E is a cooperation graph in which players i and j are not connected and H is the cooperation graph obtained from E by adding the edge that connects players i and j , then

$$\phi_i^H(v) - \phi_i^E(v) = \phi_j^H(v) - \phi_j^E(v).$$

It turns out that the Myerson value coincides with the ordinary Shapley value if the cooperation graph is the complete graph on N , and that the differences in the second condition are nonnegative when v is superadditive.

PROBABILISTIC VALUES

Let us fix some player i and, for every coalition S that does not contain player i , denote by $\alpha_i(S)$ the number $s!(n-s-1)!/n!$ where, as previously, the letter s generically denotes the number of players in coalition S . It is a simple exercise to verify that $0 \leq \alpha_i(S) \leq 1$ for every coalition S not containing player i , and that $\sum_{S \subset N \setminus \{i\}} \alpha_i(S) = 1$. Put in other terms, the family $\{\alpha_i(S) : S \subset N \setminus \{i\}\}$ is a probability distribution over the set of coalitions not containing player i . Now recall, from formula (6), that the i th component of the Shapley value can be computed by

$$\varphi_i(v) = \sum_{S \subset N \setminus \{i\}} \alpha_i(S) [v(S \cup \{i\}) - v(S)].$$

This shows that the i th component of the Shapley value is the expected marginal contribution of player i with respect to the probability measure $\{\alpha_i(S) : S \subset N \setminus \{i\}\}$ and that the Shapley value belongs to the following class of solution functions.

Definition 8. A solution function f on a subset $\mathcal{A}$ of $\mathcal{G}(N)$ is called *probabilistic on $\mathcal{A}$* if, for each player i , there exists a probability distribution $\{p_i(S) : S \subset N \setminus \{i\}\}$ on the collection of coalitions not containing i such that

$$f_i(v) = \sum_{S \subset N \setminus \{i\}} p_i(S) [v(S \cup \{i\}) - v(S)], \quad (15)$$

for every $v \in \mathcal{A}$.

The family of probabilistic solution functions embraces an enormous number of functions [13]. The efficient probabilistic solution functions are often called *quasivalues*, and the anonymous probabilistic solution functions are called *semivalues*. Since the Shapley value is anonymous and efficient on $\mathcal{G}(N)$, we know that it is both a quasivalue and a semivalue on $\mathcal{G}(N)$. Moreover, the Shapley value is the only probabilistic solution function with these properties.

Theorem 7 [Weber]. *If N has at least three elements, then the Shapley value is the unique probabilistic solution function on $\mathcal{G}(N)$ that is anonymous and efficient.*

Another widely known probabilistic solution function is the function proposed originally only for voting games by Banzhaf [14].

Definition 9. The *Banzhaf value* on $\mathcal{G}(N)$ is a solution function ψ on $\mathcal{G}(N)$ whose components at game v are defined by

$$\psi_i(v) = \sum_{S \subset N \setminus \{i\}} \frac{1}{2^{n-1}} [v(S \cup \{i\}) - v(S)]. \quad (16)$$

Again, by simple computation, we can verify that the Banzhaf value is a probabilistic solution function. Consequently, the i th component of the Banzhaf value is the expected marginal contribution of player i with respect to the probability measure $\{\beta_i(S) : S \subset N \setminus \{i\}\}$.

$\{i\}$, where $\beta_i(S) = 1/2^{n-1}$ for each subset S of $N \setminus \{i\}$.

From the probabilistic point of view, the Banzhaf value is based on the assumption that each player i is equally likely to join any subcoalition of $N \setminus \{i\}$. On the other hand, the Shapley value is based on the assumption that the coalition the player i enters is equally likely to be of any size s , $0 \leq s \leq n-1$, and that all coalitions of this size are equally likely.

The following property of total power has an important role in some characterizations of the Banzhaf value.

Property 11 [Total power]. A solution function f on a subset $\mathcal{A}$ of $\mathcal{G}(N)$ satisfies the *total power property* on $\mathcal{A}$ if

$$\sum_{i=1}^n f_i(v) = \frac{1}{2^{n-1}} \sum_{i=1}^n \sum_{S \subset N \setminus \{i\}} [v(S \cup \{i\}) - v(S)],$$

for every v from $\mathcal{A}$.

For example, we have the following analogs to Theorems 1 and 2:

- The only solution function on $\mathcal{G}(N)$ that satisfies additivity, null player, equal treatment, and total power is the Banzhaf value.
- The only solution function on $\mathcal{G}(N)$ that satisfies strong monotonicity, equal treatment, and total power is the Banzhaf value.

It is clear from formula (16) that the Banzhaf value is a semivalue on $\mathcal{G}(N)$. It is known that, if a solution function f is a semivalue on $\mathcal{G}(N)$, then, for each player i and each coalition $S \subset N \setminus \{i\}$, the corresponding $p_i(S)$ in formula (15) depends only on the number of players in S . Therefore, there exists a function γ from $\{0, 1, \dots, n-1\}$ into the unit interval $[0, 1]$ such that $p_i(S) = \gamma(s)$ for every i . We have seen that $\gamma(s) = s!(n-s-1)!/n!$ for the Shapley value, and $\gamma(s) = 1/2^{n-1}$ for the Banzhaf value.

Because the Banzhaf value is not efficient when $n > 2$, it is not suitable as the tool for

sharing benefits or costs among the members of the grand coalition. However, it may compete with the Shapley–Shubik power index when considered on various classes of simple games, for which it was originally designed. Then, it is known under different names, most often as the Banzhaf index, Banzhaf absolute index, Banzhaf–Coleman index, or Penrose–Banzhaf index.

As in the case of Shapley–Shubik index, the defining equality of formula (16) of the Banzhaf value can be simplified when considered on the class of the monotonic simple games. Let v be a monotonic simple game and let a *swing* for player i in v be defined as a pair of coalitions $(S, S \cup \{i\})$ such that S is losing and $S \cup \{i\}$ is winning. Then it is evident that formula (16) simplifies to the following analog of formula (11):

$$\psi_i(v) = \frac{\text{the number of swings for } i}{2^{n-1}}. \quad (17)$$

APPLICATIONS

Recall that the concept of a solution function on $\mathcal{G}(N)$ is just a mapping from $\mathcal{G}(N)$ into n -dimensional real linear space $\mathcal{R}^n$, and observe that every point $x = (x_1, x_2, \dots, x_n)$ in $\mathcal{R}^n$ defines a game v_x on $\mathcal{G}(N)$ by setting $v_x(S) = \sum_{i \in S} x_i$ for each coalition S . Observe that, for every x , game v_x is *additive* in the sense that, for every pair of disjoint coalitions S and T , we have the equality $v_x(S) + v_x(T) = v_x(S \cup T)$. Clearly, the collection of additive games from $\mathcal{G}(N)$ is a linear subspace of $\mathcal{G}(N)$. It follows that the solution functions can also be defined as mappings from $\mathcal{G}(N)$ into the space of additive games from $\mathcal{G}(N)$, and the Shapley value can be considered as a sensible way of transforming games from various subclasses of $\mathcal{G}(N)$ into additive games. As this or similar structures appear naturally in a variety of both practical situations and theoretical disciplines, the number of applications of the Shapley value and its variations is very large, varied, and continuously growing. The richness and diversity of these applications are convincingly illustrated in a recent survey by Moretti and Patrone [15].

Here, we briefly mention only the use of the Shapley value for the resolution of cost-sharing problems. In general, a standard game-theoretic approach to a cost-sharing problem is to design for it an appropriate cooperative game, then to analyze and solve the game in some sense and finally, to explicate the obtained solution in terms of the original problem. Typically, the players in such a game are customers of a public service, or parties who want to divide fairly the cost of establishing a common facility or undertaking a joint project.

For example, suppose that the grand coalition N is a group of potential customers of some public service, and the relevant cost data are represented through a joint cost function c defined for all subsets of N , where $c(S)$ is the cost of providing the service to the members of coalition S and where the cost of serving no one is zero. Such a game is usually called a *cost-sharing* game, and its characteristic function is denoted by c instead of the usual v .

Of course, every cost-sharing game is a usual TU game but we should note that some desirable properties of the cost-sharing games may differ from those of games in which the values of the characteristic functions are interpreted as the worth or payoff. For example, the cost-sharing games arising in practice are often not superadditive but subadditive; that is, the inequality $c(S \cup T) \leq c(S) + c(T)$ holds for every pair of disjoint coalitions S and T . However, it is always possible to associate with a cost-sharing game c another game v , called a *cost-saving* game, whose values $v(S)$ are given by $v(S) = \sum_{i \in S} c(\{i\}) - c(S)$. Then, v is superadditive if and only if the original cost-sharing game is subadditive.

Every efficient solution function of a cost-sharing game c can be interpreted in an obvious way as a method of sharing the total cost $c(N)$. If the players are to be treated fairly, then the null player and equal treatment properties of the Shapley value have a natural and attractive interpretation in the cost-sharing context:

- *Null Player*: If the cost of serving any subset of players is the same whether

a player i from N belongs to the subset or not, then player i should be charged nothing.

- *Equal Treatment*: Two players for whom the marginal cost is the same, no matter which subset of customers is served, should be charged equally.

Also, the additivity has a natural interpretation: the payment of every player for two services should be the sum of the separate payments for the two services. Thus, the Shapley value can be viewed as one of the appropriate tools for solving cost-sharing problems.

FURTHER READING

A treatment of the Shapley value for TU games is presented in almost all game theory textbooks [16–20]. However, it is almost always beneficial to also examine the origins of ideas. The original papers by Shapley and Shubik, together with a number of important subsequent papers (up to 1998) of other renowned authors, are accessible in the collection of essays edited by Roth [21]. Most of the later development can be found in Chapter 53 (by Eyal Winter) and Chapter 54 (by Dov Monderer and Dov Samet) of the third volume of the Handbook of Game Theory [22] and in the book by Peleg and Sudhölter [19]. The reader interested mainly in applications will find sufficient information in Refs 15, 23, and 24.

THE SIMPLEX METHOD AND ITS COMPLEXITY

NAGABHUSHANA PRABHU
School of Industrial Engineering, Purdue
University, West Lafayette, Indiana

Primal linear programming (LP)¹ algorithms can be divided into three families²—the *interior-point* algorithms, the *surface* algorithms, and the *exterior-point* algorithms—depending on whether the path traced by the algorithm lies inside, on, or outside the feasible region [2,3]. The simplex method, devised by Dantzig, is the most prominent surface LP algorithm. Although, the simplex method is more than five decades old, fundamental questions about the underlying geometry of the simplex method remain unanswered, making it a subject of continuing active investigation.

This article presents a brief overview of the simplex method and its complexity in the first and second sections. The latter part of the article, the third section, presents a summary of the ongoing research on the complexity of simplex-like edge-following LP algorithms. This is an introductory overview slanted toward a discussion of the outstanding problems related to the geometry of simplex method and, therefore, the details of the simplex method are presented only to the extent the details are required for the later discussion of the underlying geometric problems. The material on simplex method and its complexity, presented below, is standard lore and the reader is referred to textbooks on LP, particularly Chvatal [1], Dantzig [4], and Dantzig and Thapa [2,5], and the references therein for a more expansive discussion of the topics and pointers to the original papers.

¹Linear programming and linear program will both be abbreviated to LP.

²LP can be formulated either as an optimization or a solvability problem [1]. We focus on the optimization version.

THE SIMPLEX METHOD

A general LP can be formulated in the *canonical form* as the problem of computing

$$\min \left\{ \mathbf{c}^T \mathbf{x} \mid \mathbf{A} \mathbf{x} \leq \mathbf{b}; \mathbf{x} \geq 0 \right\},$$

where $\mathbf{c} \in \mathbb{R}^d$, $\mathbf{b} \in \mathbb{R}^m$ and $\mathbf{A}$ is an $m \times d$ real matrix. $\mathbf{c}^T \mathbf{x}$ is called the *objective function* of the LP and the inequalities the *constraints*. Each of the inequalities corresponds to a *half-space* in $\mathbb{R}^d$, and the intersection of the finite number of half-spaces is the *polyhedral* feasible region of the LP. The points in the feasible polyhedron are called the *feasible solutions* and the points at which the objective function attains its minimum value are the *optimal solutions*. In general, the underlying polyhedron can be bounded or unbounded and can be k -dimensional³ for $-1 \leq k < d$; in the following discussion we will assume that the polyhedron is bounded and d -dimensional, that is, the polyhedron is a *d-polytope*. An inequality is said to be *redundant* if dropping the inequality does not change the feasible region; in the following discussion we will make the simplifying assumption that the LP does not have any redundant constraints, in which case the boundary of each constraint determines a *facet* of the polyhedron; see Ziegler [6] for discussion on polytopes and their boundary structure.

Introducing slack variable, $\mathbf{s}$, the above *canonical form* LP can be rewritten in *standard form* as follows:

$$\min \left\{ \mathbf{c}^T \mathbf{x} \mid \mathbf{A} \mathbf{x} + \mathbf{I} \mathbf{s} = \mathbf{b}; \mathbf{x}, \mathbf{s} \geq 0 \right\}$$

If the canonical form LP does not have redundant constraints then the facets of the polyhedron correspond to the variables in the standard form LP as illustrated in the following example. Consider the LP whose

³An empty polyhedron is said to have dimension -1 .

Figure 1. The polyhedron, variable-facet correspondence and the basic feasible solutions for the LP in Equation (1).

canonical and standard forms are

$$\begin{aligned} &\text{Minimize} && [2 \ -2 \ -1] \mathbf{x} \\ &\text{S.T.} && \begin{bmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \end{bmatrix} \mathbf{x} \leq \begin{bmatrix} 1 \\ 1 \end{bmatrix} \\ &&& \mathbf{x} \geq \mathbf{0} \end{aligned} \quad (1)$$

$$\begin{aligned} &\text{Minimize} && [2 \ -2 \ -1] \mathbf{x} \\ &\text{S.T.} && \begin{bmatrix} 1 & 0 & 1 & 1 & 0 \\ 0 & 1 & 1 & 0 & 1 \end{bmatrix} \begin{bmatrix} \mathbf{x} \\ \mathbf{s} \end{bmatrix} \\ &&& = \begin{bmatrix} 1 \\ 1 \end{bmatrix} \\ &&& \mathbf{x}, \mathbf{s} \geq \mathbf{0} \end{aligned}$$

where $\mathbf{x}^T = [xyz]$; $\mathbf{s}^T = [st]$. The feasible region of the canonical form LP is shown in Fig. 1.

Setting a variable of the standard form LP to zero forces the solution to lie on the facet corresponding to the variable as shown in the table in Fig. 1. Extending the argument, a solution of the standard form LP that represents a vertex can be obtained by insisting that the solution lie on all of the facets incident at the vertex, or in other words by setting the corresponding variables to zero; see the tables in Fig. 1. The solutions of the standard form LP that correspond to vertices are called the *basic feasible solutions* (BFSs). A minimal subset of variables that

need to be set to zero to determine the vertex constitutes the set of *nonbasic variables* of the corresponding BFS and the remaining variables are the *basic variables* of the BFS. The eight BFSs of the above LP and the basic and nonbasic variables in each BFS are tabulated in Fig. 1. The correspondence between BFSs of the standard form LP and the vertices of the polyhedron is many-to-one; for example, vertex E in Fig. 1 corresponds to four different BFSs. A vertex, such as E, that is represented by more than one BFS is called a *degenerate vertex*.

The simplex method exploits the property that *if the extreme value of a linear objective function over a polyhedron is finite then the set of optimal solutions must include at least one vertex (BFS) of the polyhedron (standard form LP)*. Therefore, it searches for an optimal solution only among the finite number of BFSs of the standard form LP. Starting with an initial BFS, the simplex method computes a sequence of BFSs, such that the objective function value improves monotonically along the sequence, until it reaches an optimal BFS. The key computation in the simplex method, called a *pivoting operation*, is the construction of the next BFS in the sequence using the current BFS.

To see the details of the pivoting operation we start at the BFS corresponding to the vertex A. Partitioning the variables into two groups $\mathbf{x}_N^T = [y \ z \ s]$ and $\mathbf{x}_B^T = [x \ t]$, corresponding to the nonbasic and basic variables of the BFS 1, the equality constraints of the LP can be rewritten as

$$\begin{aligned} \underbrace{\begin{bmatrix} 0 & 1 & 1 \\ 1 & 1 & 0 \end{bmatrix}}_N \mathbf{x}_N + \underbrace{\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}}_B \mathbf{x}_B &= \underbrace{\begin{bmatrix} 1 \\ 1 \end{bmatrix}}_b \\ \Rightarrow \mathbf{x}_B &= B^{-1}(\mathbf{b} - N \mathbf{x}_N) \\ \Rightarrow \begin{bmatrix} x \\ t \end{bmatrix} &= \begin{bmatrix} 1 & -z & -s \\ 1 & -y & -z \end{bmatrix} \end{aligned} \quad (2)$$

which shows that the basic variables of BFS 1 can be expressed in terms of its nonbasic variables. In general, the matrix B that premultiplies $\mathbf{x}_B$, as shown above, is invertible for every BFS and the $\mathbf{x}_B$ of a BFS can always be expressed in terms of its $\mathbf{x}_N$. Using the expression for $\mathbf{x}_B$, in terms of $\mathbf{x}_N$, the objective function can be rewritten in terms of only the nonbasic variables as follows:

$$\begin{aligned} \mathbf{c}^T \mathbf{x} &= \underbrace{\begin{bmatrix} -2 & -1 & 0 \end{bmatrix}}_{\mathbf{c}_N^T} \mathbf{x}_N + \underbrace{\begin{bmatrix} 2 & 0 \end{bmatrix}}_{\mathbf{c}_B^T} \mathbf{x}_B \\ &= \mathbf{c}_B^T B^{-1} \mathbf{b} + \underbrace{(\mathbf{c}_N^T - \mathbf{c}_B^T B^{-1} N)}_{\text{Reduced cost coefficients}} \mathbf{x}_N \\ &= 2 - 2y - 3z - 2s \end{aligned} \quad (3)$$

The above reformulation of the objective function used the constraints in the LP and, hence, is valid only in the feasible region of the LP.

Since the nonbasic variables y, z , and s have negative reduced cost coefficients, increasing any one of them from zero while keeping the other two fixed at zero will improve the objective function value. For example, we can increase z keeping s and y fixed at zero and since x and t are to remain nonnegative, Equation (2) shows that z can be increased up to one.⁴ If we set $z = 1$

then z exits the nonbasic set (since nonbasic variables have to be zero). Since $x = t = 0$ when $z = 1$ either x or t can be added to the nonbasic set to replace z . If z is replaced by x , we get BFS 5, while if t replaces z , we get BFS 8, both of which represent vertex E. Similar reasoning shows that if, instead of z , we had chosen to remove $y(s)$ from the nonbasic set we would end up at BFS 2 (BFS 4), which represents vertex B(D).

Thus, in each pivoting operation the simplex method swaps one nonbasic variable for a basic variable. If the pivoting operation is to decrease the objective function the variable exiting the nonbasic set must have a negative reduced cost coefficient.⁵ As the preceding argument shows, at BFS 1, y, z and s are all candidates to exit the nonbasic set. The criterion used to pick the variable that will exit the nonbasic set, from among the competing candidate variables, is called the *pivot rule*.⁶ For example, if simplex method uses the *maximum increase pivot rule* then, among the competing nonbasic variables, the variable that yields the greatest improvement in the objective function will be chosen to exit the nonbasic set. At BFS 1, for example, the maximum increase pivot rule chooses z over y and s , taking the algorithm to BFS 5 (or BFS 8).

From the table in Fig. 1, we see that the only BFS that has a smaller objective function value than BFS 5 (vertex E) is BFS 3 (vertex C); so, if the algorithm is to achieve monotonic improvement then it has to move from BFS 5 to BFS 3. However, the nonbasic sets of BFS 5 and BFS 3 have only one variable in common making it impossible to move from BFS 5 to BFS 3 in one pivoting operation.⁷ So, the simplex method performs

⁵Nonnegative reduced cost coefficients for all the nonbasic variables signal that the current BFS is *optimal*.

⁶This is also called the *entering variable rule* since it only specifies which variable enters the basis but does not specify which variable, among the candidate basic variables, should leave the basis.

⁷The simplex method can go from one BFS to another in one pivoting operation only if the nonbasic sets of the two BFSs have all but one of the variables in common.

⁴If z has a negative coefficient in $\mathbf{c}_N^T - \mathbf{c}_B^T B^{-1} N$ and nonpositive coefficients in $B^{-1} N$ then it follows that the objective function can be decreased indefinitely and the LP would not have a bounded optimum.

a *degenerate pivoting operation* to move from BFS 5 to another BFS representing the same vertex E, namely BFS 6 or BFS 7, from either of which the algorithm can move to BFS 3 in one pivoting operation. The degenerate pivoting operation does not improve the objective function value but is needed to represent the degenerate vertex E with an appropriate BFS from which it can move to a better vertex.

Given an initial BFS, the pivoting operation described above can be applied repeatedly to construct a sequence of BFSs that monotonically improves the objective function value. However, since the improvement of the objective function is not strictly monotonic—as illustrated by the degenerate pivoting operation above—there is the possibility that the simplex method can cycle among the multiple BFSs that represent a degenerate vertex. Such cycling has, in fact, been demonstrated and can be avoided using an *anticycling pivot rule* [1].

The construction of the first BFS is tied to the *linear solvability problem (LSP)* [1]. Given a general system of linear inequalities S , the LSP seeks a solution of S , if one exists, or an indication that S is unsolvable, if such is the case. LSP is polynomially equivalent to LP; that is, given a polynomial-time algorithm for LSP, one can use it to devise a polynomial-time algorithm for LP and conversely [1]. Therefore, the construction of the initial BFS, is almost as “hard” as the problem of LP itself. One approach used to construct the first BFS of a given LP, L , is to solve an *auxiliary LP* that is constructed using L . The solution of the auxiliary LP yields the first BFS of L , if L is solvable, or an indication that L is unsolvable, if such is the case [1].

COMPLEXITY OF THE SIMPLEX METHOD

The time requirements of simplex method have been investigated by studying both its *average-case time complexity* as well as its *worst-case time complexity*. The average-case complexity of the simplex method, for LPs drawn from certain distributions, was shown to be polynomially bounded [7–10]; simplex has also been shown to have a polynomial *smoothed* complexity [11]. A different kind of

probabilistic analysis involves randomizing the pivot rule—that is, picking an improving nonbasic variable randomly in each pivoting operation. Such randomized pivot rules are known to have subexponential upper bounds for their expected running time [12,13]. In the following discussion we focus on the worst-case complexity of the simplex method for deterministic (nonrandomized) pivot rules.

In 1972, Klee and Minty [14] constructed a family of LPs for which they showed that the simplex method, using Dantzig’s pivot rule, performs an exponential number of pivoting operations before reaching the optimal solution. The Klee–Minty polytopes are perturbed d -cubes; Figure 2 shows a three-dimensional example (not drawn to scale) that illustrates the combinatorial behavior of simplex on the Klee–Minty LPs. A combinatorial 3-cube (d -cube) is a prism whose top and bottom facets are combinatorially equivalent to squares or 2-cubes ($(d-1)$ -cubes). The Klee–Minty LP simplex visits all the 2^{d-1} vertices of the bottom $(d-1)$ -cube, moves to the top $(d-1)$ -cube and visits all the vertices of the top facet in the reverse order, thereby performing 2^{d-1} pivoting operations in all. The simplex method visits every vertex in the Klee–Minty LP even though the optimal vertex is adjacent to the initial vertex and it is possible to reach the optimal BFS from the first BFS in *one* pivoting operation, using the *maximum improvement pivot rule*⁸ instead of *Dantzig’s pivot rule* [14].

The Klee–Minty LP raised the question of *whether it is possible to make the simplex method a worst-case polynomial-time algorithm by employing a good pivot rule*; the question remains unanswered to this day. All the (nonrandomized) pivot rules whose complexities have been analyzed are known to require exponential time in the worst case; see papers [15–22] for details.⁹ Zadeh [25] made the observation

⁸Pick the nonbasic variable that yields the greatest improvement in the objective function value.

⁹In fact, even the gravitational method [23], which is not constrained to traverse the edge-graph of the polyhedron, was shown to behave like the steepest descent pivot rule and has exponential worst-case complexity [24].

Figure 2. Simplex's trajectory on a three-dimensional Klee–Minty LP.

that the structure of the polytopes used to establish the worst-case exponential-time behavior of the analyzed pivot rules have the so-called *deformed product structure*¹⁰ and proposed a pivot rule—the *least entered pivot rule*¹¹—that was devised to avoid the pathological behavior on deformed product polytopes. The question of whether Zadeh's pivot rule makes the simplex method a worst-case polynomial-time algorithm remains open.

POLYHEDRAL DIAMETER AND THE # FUNCTION

For vertices u and v in a polyhedron P , let $\delta_P(u, v)$ denote the length¹² of the shortest

edge-path between u and v . Further, let $\delta(P)$ denote the *edge-diameter* of P , that is, the maximum value of $\delta_P(u, v)$ over all pairs of vertices (u, v) in P . Clearly, between every pair of vertices in P there is an edge-path of length of at most $\delta(P)$. The diameter functions Δ and Δ_b are defined as

$$\Delta(d, n) := \max \{ \delta(P) \mid P \text{ is a } d\text{-polyhedron} \\ \text{with } n \text{ facets} \}$$

$$\Delta_b(d, n) := \max \{ \delta(P) \mid P \text{ is a } d\text{-polytope} \\ \text{with } n \text{ facets} \}.$$

While a polynomial upper bound on $\Delta(d, n)$ does not guarantee the existence of worst-case polynomial-time pivot rule, a superpolynomial lower bound on $\Delta(d, n)$ will preclude the existence of a worst-case polynomial-time pivot rule. Hence sharp upper and lower bounds on $\Delta(d, n)$ are of interest in the context of the quest for a worst-case polynomial-time simplex algorithm. Although, neither a polynomial upper bound nor a superpolynomial lower bound has been established for $\Delta(d, n)$, the last five decades have witnessed accumulation of both theoretical and empirical results related to the diameter functions.

On the basis of the performance of the simplex method on thousands of practical LPs, Dantzig [4, p. 160] observed that if the basic set of an LP has m variables, and the initial and optimal BFSs have k basic variables in common, then the number of simplex steps is “usually close” to $m - k$; further, he added that for $k = 0$, the number of iterations rarely exceeded $3m$. Forty years later, Dantzig and Thapa [5, p. 31] reiterated the observation that simplex usually requires fewer than $3m$ iterations for problems in which the basic set has m variables. For additional computational results, see Bixby [26, 27].

The good practical performance of the simplex method and the polynomial bounds on the average-case complexity would not be surprising if polyhedra indeed have a *large number of short edge-paths* between every pair of vertices. In fact, the famous Hirsch conjecture [4] asserts that $\Delta(d, n) \leq n - d$ while the weaker *polynomial diameter conjecture* (PDC) [28] asserts that $\Delta(d, n) \leq P(d, n)$, where $P(d, n)$ is some polynomial of d and

¹⁰ The deformed product polytopes have the combinatorial structure of the form $P_d \times P_k$ where P_d (P_k) is a d -polytope (k -polytope), and k is a small number. The Klee–Minty d -polytopes are of the form $C_{d-1} \times P_1$ where C_{d-1} is the $(d - 1)$ -cube and P_1 is a line segment.

¹¹ Among the competing nonbasic variables Zadeh's *least entered pivot rule* chooses the nonbasic variable that has entered the basic set (exited the nonbasic set) least often.

¹² The length of an edge-path is the number of edges in the path.

n . The Hirsch conjecture remains open for bounded polyhedra, while the *PDC* remains open for both bounded and unbounded polyhedra.

While the diameter function provides an upper bound on the length of the shortest edge-path between two vertices, it does not contain complete information about the number of edge-paths, between the vertices, of length less than or equal to the bound provided by the diameter function. Interest in the number of paths suggests, in addition to $\Delta(d, n)$, the function $\#_f(d, n)$, defined as *the greatest lower bound on the number of edge-paths of length $f(d, n)$ or less, between a pair of vertices in a d -polyhedron with n facets, where $f(d, n)$ is a specified function of d and n* . In terms of the $\#$ function, the Hirsch conjecture can be stated as the claim that $\#_{n-d}(d, n) \geq 1$ and the PDC as $\#_{P(d, n)}(d, n) \geq 1$, for some polynomial function $P(d, n)$.

Progress in our understanding of the diameter functions has been rather modest and even less is known about the $\#$ function. We summarize the prominent results below; the reader is referred to Kalai [29], Kim and Santos [30], and Klee and Kleinschmidt [31] for a more complete survey of the results about the diameter functions.

The Hirsch conjecture is known to hold for $d = 3, n \geq 4$ [32]. The Hirsch conjecture fails for unbounded 4-polyhedra with 8 facets and further the departure from the Hirsch bound for general polyhedra tends to infinity as $\min(d, n - d)$ increases [33]. Specifically,

- $\Delta(d, n) \geq n - d + \min \left\{ \left\lfloor \frac{d}{4} \right\rfloor, \left\lfloor \frac{n-d}{4} \right\rfloor \right\}$ [33].

The Hirsch conjecture for bounded polyhedra (polytopes) is still open. The following results are known for $\Delta_b(d, n)$.

- $\Delta_b(d, n) \leq n - d$ for $n \leq d + 5$; $\Delta_b(d, 2d) = d$ for $d \leq 5$ [33].
- $\Delta_b(d, n) \leq n - d$ for $n = d + 6$; $\Delta_b(d, 2d) = d$ for $d = 6$ [34].
- $\Delta_b(4, 10) = 5$; $\Delta_b(5, 11) = 6$ [35]. $\Delta_b(4, 11) = 6$ [34]; $\Delta_b(4, 12) = 7$ [36].
- $\Delta_b(d, n) \geq n - d$ for $d \geq 7$, that is, the Hirsch bound is sharp [37–39].

- $\Delta_b(d, n) \leq n2^{d-3}$ [40].

For the general case the best known upper bound is

- $\Delta(d, n) \leq n^{\log d + 2}$ [28].

The Hirsch conjecture has been reformulated as several equivalent conjectures, the details of which, including the proofs of equivalence, can be found in Klee and Kleinschmidt [31]. For example, the seemingly less general d -step conjecture, which claims that $\Delta_b(d, 2d) = d$ for all d , is known to be equivalent to the bounded Hirsch conjecture. Of particular interest is the *Gaussian elimination sign conjecture* (GESG), which is equivalent to the bounded Hirsch conjecture and particularly well-suited for investigating the $\#_d(d, 2d)$ function for bounded polyhedra [41]. The GESG invokes the $(d - 1)$ -dimensional representation of the symmetric group $\text{Sym}(d)$ on d letters.¹³ Specifically, if $\tau \in \text{Sym}(d)$, then define the $(d - 1) \times (d - 1)$ matrix Q_τ as

$$(Q_\tau)_{i,j} = \begin{cases} 1 & \text{if } \tau(i) = j \leq d - 1 \\ 0 & \text{if } \tau(i) \neq j \text{ and } 1 \leq \tau(i) \leq d - 1 \\ -1 & \text{if } \tau(i) = d. \end{cases}$$

$S_{d-1}(d) = \{Q_\tau \mid \tau \in \text{Sym}(d)\}$ is a $(d - 1)$ -dimensional representation of $\text{Sym}(d)$. Using $S_{d-1}(d)$ the notion of a *general position* $(d - 1) \times (d - 1)$ matrix is defined as follows. A $(d - 1) \times (d - 1)$ matrix M is said to have a *nondegenerate triangular factorization* if M can be written in terms of a lower triangular matrix L and an upper triangular matrix U as,

$$M = L^{-1}U, \text{ where } L_{i,j} \neq 0 \text{ iff } j \leq i; L_{k,k} = 1, \\ 1 \leq k \leq d - 1; U_{i,j} \neq 0, \text{ iff } i \leq j.$$

The above nondegenerate triangular factorization is said to be a *positive triangular factorization* if the nonzero elements of the matrices L and U are positive. A $(d - 1) \times$

¹³ $\text{Sym}(d)$ is the group of all permutations of $(1, 2, \dots, d)$.

$(d-1)$ matrix M is said to be in *general position* if all the $(d!)^2$ matrices $Q_\sigma M Q_\tau$, $\sigma, \tau \in \text{Sym}(d)$ have nondegenerate triangular factorizations. The GESC states that *for every $(d-1) \times (d-1)$ general position matrix M there exists at least one pair $(\sigma, \tau) \in \text{Sym}(d) \times \text{Sym}(d)$ for which $Q_\sigma M Q_\tau$ has a positive triangular factorization.*

Klee and Walkup showed that $\Delta_b(d, 2d)$ can always be realized as the length of the edge-path between the antipodal vertices of a d -dimensional Dantzig figure [33, Theorem 2.8]; a d -dimensional Dantzig figure is a triple (P, u, v) where P is a simple d -polytope with $2d$ facets, and u, v are two specific *antipodal* vertices in P —that is, vertices that do not have any incident facet in common. The $(d-1) \times (d-1)$ general position matrices M mentioned in *GESC* correspond to d -dimensional *Dantzig figures*. Every pair $(\sigma, \tau) \in \text{Sym}(d) \times \text{Sym}(d)$ that yields a positive triangular factorization of M corresponds to an edge-path of length d between the antipodal vertices of the associated Dantzig figure [41, Theorem 5.1]. Therefore, the number of pairs (σ, τ) that yield positive triangular factorizations of a given $(d-1) \times (d-1)$ general position matrix M , denoted $\#^D(M; d)$, gives the number of edge-paths of length d between the antipodal vertices of the corresponding Dantzig figure.¹⁴ Further, let

$$\#^D(d) := \min \left\{ \#^D(M; d) \mid M \text{ is a } (d-1) \times (d-1) \text{ matrix in general position} \right\}.$$

Computational experiments suggested that $\#^D(d) \geq 2^{d-1}$, an inequality that was stated as the *strong d -step conjecture* [41]. The above inequality was shown to hold as an equality for the two extreme cases—Dantzig figures where P is either the dual of a cyclic polytope [which has the maximum number of vertices among $(d, 2d)$ polytopes] or the truncation polytope [which

has the minimum number of vertices among $(d, 2d)$ polytopes] [42]. The inequality also holds for $d \leq 4$ [41, 43]. Holt and Klee [39] showed that the inequality fails for $d \geq 5$ by constructing Dantzig figures for which $\#^D(M; d) = (\frac{3}{4}) 2^{d-1}$. More recently $\#^D(d)$ was shown to have an asymptotic upper bound of $O((1.8882)^d)$ [37]. The empirical experience with the simplex method [4, 5], the computational results about $\#^D(d)$ [41] and the results of [37, 41–43] suggest the question:

$$\text{Is } \#^D(d) \geq a^{d-1} \text{ for some } a > 1?$$

The answer is in the affirmative for $d \leq 4$ and the question is open for $d \geq 5$.¹⁵

THE STRATEGIC CHOICE APPROACH

JOHN FRIEND
Stradspan Limited, Sheffield, UK

The *Strategic Choice Approach* (SCA) is a name that has become attached to a balanced collection of tools and concepts developed by management scientists to facilitate communication about the structuring of perplexing decision problems, and also about strategies for making progress toward timely commitments to agreed actions. The tools are primarily visual in form, yet are linked at an analytical level through a distinctive philosophy that draws on insights into how decision makers can learn to manage diverse sources of uncertainty in a strategic way. This philosophy reflects an interpretation of the practical challenges of interactive planning under real-time action pressures, as observed by management scientists working alongside their social science colleagues.

APPLICATIONS

The tools of SCA have now been successfully introduced to support people facing challenging decision problems in many contexts of management, at levels ranging from local community action to national policy development. In many instances, these tools are not employed by management science professionals but by project managers, consultants or programme coordinators with responsibility for facilitating decision processes in fields as diverse as environmental conservation, information technology strategy, urban development, product marketing, and health and welfare policy.

The approach has now been adapted for application in a wide range of cultural contexts. It is frequently used to facilitate interagency workshops, which are designed to bring together diverse organizational

and stakeholder interests; at other times, it is introduced to guide communication in more informal management settings, with optional computer support. Some users choose to apply the tools in combination with qualitative or quantitative methods drawn from other toolkits with which they are familiar. This reflects the exploratory spirit of action research that has governed the evolution of the approach since it was pioneered by a group of operational research scientists in Britain some four decades ago.

ORIGINS

The origins of the approach are to be found in the early project experiences of the *Institute for Operational Research* (IOR) in the Tavistock Institute of Human Relations in London. This was an initiative of the Council of the UK Operational Research Society in partnership with the Council of the Tavistock Institute, which is an independent not-for-profit institute in London dedicated to the application of the social sciences to important societal issues. The IOR was launched in 1963 under the direction of the late Neil Jessop, as a semiautonomous unit within the Tavistock matrix [1].

SCA grew out of two of IOR's seminal projects, both conducted by mixed teams of OR and social scientists. One of these projects addressed issues of communication in the building industry, while the other explored the processes of policy making and planning in city government. Between the early 1970s and the mid-1980s, IOR teams went on to conduct a range of further research and consulting projects, many of them addressed to public policy issues and processes under the auspices of government agencies in the United Kingdom and overseas.

Since then, the practice and theory of the approach has been further developed through projects and programmes in countries as far apart as Canada, the Netherlands, Brazil, Japan, Sweden, Venezuela, and

Italy, in many cases involving collaboration between local champions and members of the original “IOR School.” Several references are found in the third edition of the core textbook by Friend and Hickling, *Planning under Pressure* [2].

FOUNDATIONS OF THE APPROACH

SCA is one of the six main approaches to problem structuring presented in the book *Rational Analysis for a Problematic World Revisited* [3], which is recognized as the leading guide in this field. It has now established its place as one of the most widely applied of the new interactive approaches to what is sometimes called *qualitative OR*. It can be distinguished from other OR approaches, both soft and hard, with reference to a summary of its principal *emphases*.

Emphases of the Strategic Choice Approach

The distinctive emphases of SCA reflect its origins in extensive observation and facilitation of group decision processes. These emphases can be expressed in terms of the following five key dimensions.

Focus: more emphasis on *facilitating decisions* than *exploring systems*;

Knowledge: more emphasis on *managing uncertainty* than *processing information*;

Time: more emphasis on *sustaining progress* than *projecting futures*;

Skill: more emphasis on *structuring communication* than *reinforcing expertise*;

Influence: more emphasis on *guiding collaboration* than *exercising control*.

The emphasis on *facilitating decisions* serves to distinguish SCA from those approaches that aspire to take a broader, more synoptic view of systemic influences. The emphasis on *managing uncertainty* can be seen as the most distinctive feature of SCA, leading to a focus on the *strategic management of uncertainty through time*. The emphasis on *sustaining progress* reflects the observed reality that the management

of interdependent choices tends to be an incremental process, in which it can be more realistic to make progress step by step than to attempt to design a more comprehensive planning framework.

The final two emphases, on *structuring communication* and on *guiding collaboration*, reflect the observation that, the more interconnected the choices to be addressed become, the wider the range of interests and responsible decision makers that tend to be drawn in. So it becomes important to build capacities to reach out toward other decision makers, understanding the contexts and constraints within which they work and negotiating collaborative links—across organizational boundaries as well as within corporate settings.

Managing Uncertainty in a Strategic Way

One of the most important observations from the city government project was that, whenever a challenging issue arose on a group agenda, people tended to argue for different ways of overcoming the challenge, as shown in Fig. 1.

In such a situation, some people might argue for a relatively *technical* response, through some form of investigation—ranging from a quick telephone call to an expert to a more formal commissioning of some kind of survey, analysis, forecasting, or research. Other people meanwhile might argue for a more *political* response, perhaps in the form of a review of objectives, policies, goals, or priorities within some accountable group; or perhaps a consultation with representatives of any professional or community interests that will be affected by the decisions to be made. Other people again might argue for a more *structural* response, broadening the agenda to take into account other related choices, and thus moving toward placing the choice within a wider planning framework.

In Fig. 1, these three types of response are expressed in terms of calls for “deeper investigations,” “clearer policies,” and “broader perspectives,” respectively. Each of these in turn is interpreted as a response to a different kind of *source of uncertainty*.

The figure identifies three broad categories of uncertainty as follows:

Figure 1. Sources of uncertainty in strategic choice.

Uncertainties concerning our working Environment (UE);

Uncertainties concerning our guiding Values (UV);

Uncertainties concerning choices to be made on Related agendas (UR).

It is usually not hard to agree that the reduction of significant sources of uncertainty in any of these directions is a desirable aim. Yet, wherever there are pressures on time or other resources, it can be a more controversial matter to agree on how much time and effort should be invested in actions directed at any one category of uncertainty rather than another.

Therefore, questions arise about how much *investment* of time and other resources should now be made in explorations directed toward different sources of uncertainty—broadly technical, political, and structural. These are the questions that many experienced decision makers learn to consider in an intuitive way; yet, they are rarely addressed explicitly at times when people meet to consider jointly what they should do in a specific situation, under some current combination of pressures on time and resources.

Whatever agreements may be agreed upon about actions to reduce uncertainty, these actions can have a profound influence not

only on the choices to be made on the current agenda but also on future paths of decision making. Because, depending on the choices made as to which particular package of investigations, policy consultations, or negotiations should now be set in train, different people may become involved at different times and through different channels. Hence decision making does not merely become a *process* in a sequential sense but rather an ever-shifting lattice of partially intertwined activities in which patterns of participation may shift over time in complex ways.

Therefore, while pressure to take decisions can be regarded as the primary force that drives the dynamics of choice, the *planned management of uncertainty through time* can come to play an important supporting role in shaping the agendas of the decision makers. This is why it is only realistic to view the management of uncertainty as an important secondary driver in any activity of strategic—as opposed to simple—choice.

Four Key Aspects of Decision Making

In presenting the more specific set of concepts, methods, and tools that characterize SCA, it is useful to introduce a general model of decision making that identifies four complementary aspects or *modes* of decision making. These are presented in Fig. 2 as the *shaping, designing, comparing, and choosing*

Figure 2. Four modes of decision making.

modes. They are presented here as stages in a cycle, with opportunities at any stage to revisit earlier modes.

In any simple context of decision making, where it is expected that choices in different areas of decision will be made one at a time according to prescribed guidelines, the only two significant modes are those indicated in the lower part of Fig. 2. Because, within a clear problem focus, it is sufficient to *design* some set of options to be considered, then to *compare* them in order to arrive at a preference. Sometimes, the options to be compared may be clear-cut—yes or no, this response or the other—while at other times more effort may be needed to *design* a range of feasible options. Likewise, in *comparing*, sometimes it may be clear which option is to be preferred, while at other times a careful evaluation may be required to judge which option will perform best within current guidelines. Wherever there is significant uncertainty over this, a loop back to the *designing* mode may be helpful in order to introduce further design options.

It is where there are a number of interrelated choices to be made that the two further modes of decision making shown in the upper half of Fig. 2—*shaping* and *choosing*—start to demand at least as much attention as the

more basic modes of designing and comparing. This is especially so where people bring to bear different perspectives on the nature of the decisions to be made and the configuration of links between them.

The challenge becomes all the greater where these linked areas of choice cut across different organizational or program agendas. It can now become harder to agree what areas of choice should be considered, in what words they should be expressed, and to what extent they are interlinked. Further, a collective judgment is required as to what should be the focus of concern at this stage—even accepting that it may be possible to alter such a focus by agreement later, as progress is made on the more urgent choices, and as new priorities emerge.

In such a situation, the mode of *choosing* can also become more challenging because a balance now has to be struck between areas within the present focus where decisions are to be made now, and those where choice can be deferred until some future time, while judgments are also needed regarding which areas of uncertainty are to be addressed now to increase confidence in future choices. Where there are many stakeholders, the striking of these balances can become

especially challenging, in both technical and political terms.

The concept of a *progress package* is found helpful as a means of assembling the outcomes of any cycle through the four modes. It can be presented in a simple grid format, distinguishing between decisions to be made *now* and those to be addressed at some point in the *future*, while also distinguishing between actions addressed to substantive decision areas and *exploratory* actions in response to key areas of uncertainty, as follows:

- Now: decisions agreed in some areas of choice;
explorations agreed for some areas of uncertainty.
- Future: other areas of choice in which decisions have not yet been agreed to;
other areas of uncertainty in which no explorations have been agreed.

The more challenging a process of strategic choice becomes, the more important it becomes to develop capacities to switch flexibly between one process mode and another, depending on judgments as to where the most immediate opportunities for progress are currently to be found. This is indicated in Fig. 2 by the inclusion of a loop linking each mode to each other mode, whether earlier or later in the cycle. In a group context, this kind of judgment calls for a subtle process of *facilitation*, in which the facilitator—or facilitation team—must balance a sensitivity to the dynamics of group interaction against a concern to sustain progress over the time remaining within the current session.

INTRODUCING THE TOOLS OF THE STRATEGIC CHOICE APPROACH

The sections that follow introduce, in the logical sequence of four modes introduced in Fig. 2, the set of basic concepts and visual tools that have been developed to support the application of SCA.

It would be unhelpful for us to present these concepts and tools purely in abstract terms. Therefore, they are brought to life

through an example of a situation that is presented as being small in scale and urgent, yet which illustrates the sorts of interconnected choices, uncertainties, options, and criteria that typically arise in broader planning contexts. The presenting situation is described briefly as follows:

PDQ is a management consulting group with 12 staff, which recently tendered to undertake a management review for a nearby public authority. The decision has been unexpectedly delayed for 4 months; then PDQ are unexpectedly offered the contract. *How are they now to respond, in a changed situation where some members of the proposed project team have now become committed to other assignments?*

Tools for Shaping Difficult Problems

The fundamental concept that is used to guide the work of the shaping mode is that of the *decision area*. A group of decision makers may agree to express any area of choice that they see ahead of them as a decision area if they can visualize at least two distinct *options*, and if they expect to have some level of influence in choosing between them.

The principal output of work in the shaping mode takes the form of a *decision graph*, in which significant connections between pairs of decision areas have been identified in the form of *decision links*. Where there are many interlinked decision areas, an important next step is to select a subset of these as an agreed *problem focus* before proceeding to develop and compare possible ways forward.

In logical terms, the task of shaping a decision problem in this way is very simple. Yet, as users of SCA soon discover, the art of applying these simple tools in practice can be far from straightforward. This is especially so where a workshop brings together a diverse group of participants, all with different perspectives and stakes in the current problem situation. The initial challenge is then to capture the perceptions about currently significant areas of decision, which the participants bring with them in their heads.

Figure 3 illustrates this by an example of the type of record that might be built up

about the PDQ consulting contract in the initial stages of discussion in the *shaping* mode. Figure 3a depicts an initial list of decision areas, such as might be written by a facilitator on a flip chart in response to suggestions from the group. A skilled facilitator writes legibly in freehand, using a broad-tipped colored marker pen—pausing at times to suggest shorter forms of words and to check that these capture the intended meaning. A question mark after the description of each decision area is useful as a reminder that each entry is intended to represent an *area* of choice, rather than some preferred course of action within that area.

An initial list of decision areas may cover more than one sheet of paper. Sometimes the facilitator may suggest that a proposed addition to the list may be better expressed not as a *decision area* but as an *uncertainty area*—possibly because it is more realistically treated as a matter for investigation rather than choice. Other suggestions may be better expressed as *comparison areas*, because they can more realistically be seen as high-level objectives or goals than as areas of choice between specific alternatives.

Therefore, in Fig. 3, the proposed entry *impact on our reputation* is shown struck through, to be transferred to a parallel list of comparison areas for later consideration. Similarly, the two entries “Whether to bid for HKI project?” and “Value to us of public sector work?” might be transferred to another parallel list of *uncertainty areas*, to be sorted later into the three categories indicated in Fig. 1. Some people might see the use of strikethrough lines as untidy, but it has value where it records an important moment in a group learning process.

It is worth observing here that SCA differs from more hierarchical approaches to strategic planning in not treating objectives as starting points but as criteria for comparison—and also perhaps as sources of uncertainty about values to be addressed if and when their significance to decisions becomes more evident.

Once agreement has been reached on a set of decision areas to be considered further, a shorter label for each can be chosen. If this is written on a semiadhesive sticker, as shown in Fig. 3, then it can be transferred to a blank flip chart as a candidate for inclusion in a decision graph. Figure 3

Figure 3. Tools for shaping problems.

illustrates the use of large elliptical stickers, which, while not essential, are especially convenient for this purpose; sources of supply can be located through www.ovalmap.com. The facilitator can begin moving the stickers around, with guidance from other participants, clustering together those that seem closely related until a good-enough first representation of the “shape” of the problem has been agreed. Then connecting lines—as straight as possible—can be added between pairs of decision areas that are agreed to be directly interlinked. In this visual mapping method—sometimes called *AIDA* for *Analysis of Interconnected Decision Areas*—the use of arrowheads to indicate directed links is not recommended, as questions of sequence and influence are handled in other ways.

As a further aid to selection, color coding can be introduced, as shown in Fig. 3, to identify any decision areas that are agreed to be more *important* or *urgent* than others. Then a boundary can be drawn to enclose those areas—preferably not more than three or four—which have been agreed as an initial *problem focus*. Exclusion from this initial focus does not preclude the reintroduction of decision areas later.

Where the number of decision areas is more than around 10, there may be merit in introducing more formal methods of analysis to help in agreeing on a focus, thus reducing the potential for bias from the use of visual methods alone. Computer methods may be helpful here—for examples see www.stradspan.com—so long as they do not disrupt the dynamics of the group. Users sometimes supplement these quick and intuitive methods of problem shaping by introducing mapping methods from other toolkits with which they are familiar. Several of the examples presented in *Planning under Pressure* [2] illustrate the potential for mixing methods in this way.

Tools for Designing Feasible Strategies

In the *designing* mode, the amount of effort required to develop a range of feasible strategies depends on the number of decision areas included within the current focus. Where the focus is restricted to a single decision area, the task is merely to agree to a set of two

or more feasible *options* within that decision area, which can be taken as a sufficient representation of the range of choice available. It is recommended that the number of options be limited to four or five at most, expressed where possible so as to be mutually exclusive. Occasionally, this may mean selecting a few representative points on a continuous scale.

Where the chosen focus embraces two or more linked decision areas, the process of devising a set of feasible courses of action—or strategies—becomes less simple because now it becomes necessary to consider combinations of options, one from each decision area, recognizing that some combinations may be *incompatible* for various reasons.

For example, in the PDQ case, it may be agreed upon that the three possible contenders for *Leader* of the team are *Ana*, *Bernard*, or *Colin*—with the knowledge that *Ana*, despite being originally named as leader of the team, is now less available than she was previously. It may also be thought that her senior colleague *Bernard* has less relevant skills; while their former colleague *Colin* now works for another employer, yet might be brought back to lead the team if contractual arrangements could be agreed upon. Because the inclusion of a second *Senior* team member in the team is considered optional, the options here are agreed to be *none*, *Ana*, or *Colin*. Then it may be agreed that the choice of project *Methods* be restricted to *traditional* or *group*—perhaps after some discussion of whether it might also be acceptable to suggest to this client a third option of *mixed methods*.

Once the agreed set of options in each decision area has been agreed and recorded—typically on a single flip chart—it remains to review the *mutual compatibility* of combinations of options from different decision areas. Figure 4a illustrates this in the case of PDQ by showing the incompatibilities displayed on a flip chart in terms of a set of *compatibility tables*—or matrices—one for each pair of decision areas. Alternatively, they can be displayed by expanding the decision graph into a more detailed *option graph* format [2, p.36]. In Fig. 4, an X symbol is used to indicate

Figure 4. Tools for designing strategies.

incompatibility, while doubtful compatibility is indicated by a question mark. The use of an X is found to make for easier dialogue with nonmathematicians than the more conventional 0/1 symbols.

The reasoning behind each assumption of incompatibility may differ. For example, the inclusion of Ana as both leader and senior support person is here ruled out on logical grounds, while the choice of Bernard with no senior support is excluded here because of a judgment of his limited experience; and the choice of Colin with no senior support may be excluded because it would limit PDQ influence. The question mark over the use of group methods by Bernard reflects his limited experience in this field. It is useful to record the logic behind each assumption somewhere where it can be challenged later on.

The impact of any set of assumptions on the range of choice available across all the decision areas in focus can be explored through developing what is called an *option tree*, as shown in Fig. 4b. This involves taking the decision areas in any agreed sequence then, as each option is added, checking its compatibility with the option selected in each of the preceding decision areas. Figure 4 makes the logic explicit by

marking each closed or “dead” branch with a cross. The result in this instance is that, of the 18 theoretical combinations, only 7 are available—further reduced to 5 if questionable compatibilities are excluded. Where there are more than three decision areas in focus, this process of logical testing can be a time-consuming one, unless computer support is available. This is one reason why it is recommended that in a workshop the problem focus be restricted to only a few decision areas at a time.

The number of feasible combinations or *decision schemes* is, of course, unaffected by the sequence in which the decision areas are reviewed. However, the choice of sequence does affect the way in which structural information is displayed. For instance, the positioning of the Leader decision at the front of the tree shows that, if this is most urgent decision, then the choice of Ana will preempt all paths except one in the other decision areas, while the choice of Bernard will leave more future paths open.

Tools for Comparing Impacts under Uncertainty

As a foundation for making structured comparisons among the possible ways forward,

SCA introduces the basic concept of a *comparison area*—broadly equivalent to the familiar term *criterion*, which is indeed sometimes substituted for brevity.

Depending on the knowledge available, initial comparisons can be made either between options within a single decision area or between decision schemes spanning a set of linked decision areas. It is usual for a facilitator to start listing comparison areas on a separate flip chart from the outset of a workshop, side by side with the sheets used to record decision areas and uncertainty areas. It is normally sufficient to work with a set of between four and eight comparison areas, provided the concerns of all significant stakeholders or interest groups are recognized. Figure 5a shows a set of four comparison areas that might have been agreed upon in the PDQ case. In this instance, it is assumed that the debate has resulted in the substitution of one suggested comparison area (*contribution to profit*) by another (*contribution to cash flow*) as a preferred indicator of financial impact.

Figure 5b illustrates a visual method that has been found powerful as a means of helping a group of participants to compare *pairs* of options or schemes in terms of the perceived balance of advantage between them. This approach introduces a qualitative scale of *comparative advantage*, in which an agreed set of adjectives—marginal, significant, considerable, and extreme—is used to indicate perceived levels of advantage to either side. This forces the participants to make subjective judgments as to the relative importance of different comparison areas *in relation to their present decision situation*. So both tangible and more intangible considerations can now be brought together within a shared value framework, offering opportunities for negotiation within the group and enabling judgments to be made both within and across comparison areas.

In Fig. 5, small semiadhesive stickers are used to agree to a range of possibilities for the relative advantage between the alternatives on the comparative advantage grid, taking the comparison areas one at a time and then aggregating them. For each comparison area, discussion can then focus on

the range of possible advantage to either side, as well as the most likely position. In this instance, the judgment is that scheme 3, with Bernard as leader, is likely to have significant advantages in terms of cash flow and staff development. These are judged to outbalance the more marginal advantages of scheme 1, with Ana as leader, in terms of reputation and flexibility—remembering however that scheme 3 is subject to doubts about the capacity of Bernard to handle group methods.

The use of this kind of comparative advantage grid usually brings to the surface further areas of uncertainty relating to guiding values (UV in the strategic choice language), as well as uncertainties of types UE and UR. Therefore, this helps in building a base from which to begin considering the overall impact of uncertainty on decisions, leading into discussion of opportunities for managing the most critical areas of uncertainty in a collaborative way.

Similar comparisons might now be made between other pairs of decision schemes among the seven shown in Fig. 4. Since it can become time consuming to compare all feasible pairs of schemes in the same depth, crude methods of shortlisting are often introduced to reduce the range of pair comparisons. One approach is to look for schemes that appear to be dominated by other schemes in terms of critical comparison areas; another is to rule out those that transcend some maximum or minimum level on some of the more quantifiable criteria such as cash flow. Another approach is to aggregate separate assessments for options within decision areas as a starting point in comparing schemes. All these approaches mean temporary suppression of information about critical areas of uncertainty, accepting that these can then be explored in more depth for selected pairs.

The phrase *dynamic comparison* is sometimes used to describe a cycle in which periods of crude comparison among many schemes alternate with periods of closer pair comparison, in which some schemes may drop out while new areas of uncertainty may be revealed.

Figure 5. Tools for comparing under uncertainty.

Tools for Managing Uncertainty and Sustaining Progress

Once the most critical areas of uncertainty have been exposed, it becomes possible to discuss whether any possible *exploratory actions* can be identified to reduce their impact on the important decision areas within the present focus.

Even where a list of significant uncertainty areas has been built up from the start of a workshop, it is a good discipline to review and restructure the list when first moving into the choosing mode, to facilitate debate about any ambiguities or overlaps that may have arisen. An opportunity now arises to review the classification of each uncertainty area in terms of the three categories UE, UV, and UR, accepting that there may be some borderline cases. At this time,

symbols can also be introduced to indicate the relative *prominence* of each uncertainty area in relation to the decisions currently in focus—recognizing that this rating may have to be reviewed later if the problem focus is changed.

Among analytical participants, a bias is now likely to emerge toward sources of uncertainty of type UE that can be expressed in quantitative or probabilistic terms. Other people however may be more sensitive to political uncertainties, suggesting response in terms of policy consultations (UV), while others again may be aware of uncertainties about the intentions of other parties, prompting a more negotiative response of type UR. In the PDQ case, some key uncertainty areas that might now be identified are as shown below

- ? Will Colin be available for this project **?COLIN FREE** **UE +++**
 Exploratory options: *phone him at home; ask at next week's meeting; [no action]*
- ? Whether PDQ is to bid for HKI project **?HKI BID** **UR +**
 Exploratory options: *place on Board agenda; informal soundings; [no action]*
- ? Value to PDQ of bidding for public sector projects **?VAL PUB** **UV ++**
 Exploratory options: *policy debate; [no action]*
- ? Can Bernard handle group methods **?BERN SKILL** **UE ++**
 Exploratory options: *trial workshop; skill tests; [no action]*

Figure 6. Tools for agreeing a way forward.

Each uncertainty area is here shown with a question mark placed *in front*—a convention used to distinguish it from a decision area—while its full description is followed by a briefer working label. Each area is also classified into one of the UE/UV/UR categories, and is given an agreed rating of *prominence* on a scale relating to the current problem focus.

Any views on possible *exploratory options* are then noted against each uncertainty area, recognizing that these can always be compared to a *null option* of taking no action. Therefore, both within and across uncertainty areas, judgments of relative value can now be made for all possible exploratory actions, each compared to the null option. Any expected benefit of an exploratory option in terms of improved *confidence* in decision making can then be balanced—however subjectively—against its expected *costs* in terms of financial or other resources, together with any penalties associated with *delay* in significant future decisions.

At a stage when a group is moving toward a point of pressure to agree on early

decisions or recommendations—as in the closing stages of a workshop session—then it is useful to introduce the framework of the *progress package grid*. A facilitator begins by posting on the wall a blank grid of the form shown in Fig.6, usually spread across two or more flipcharts side by side so as to leave space for additions and alterations. Its function is to facilitate agreement regarding the balance between those decision areas in which it is agreed to make or recommend action *now*, and those others in which commitment is to be deferred until some *future* time. This in turn raises questions about which uncertainty areas are to be addressed now through the choice of some exploratory option—explicitly recognizing, in the final column, the alternative of choosing not to take any such steps.

Figure 6 illustrates for the case of PDQ how semiadhesive stickers can be used to facilitate discussion about the allocation of both decision areas and uncertainty areas either to the *Now* or the *Future* half of the grid. It is often also useful to divide the grid

into rows to indicate different areas of responsibility. While compiling the grid, the facilitator can encourage the participants to refer flexibly to their records of earlier progress in other modes, as displayed on flipcharts elsewhere in the room. For example, when considering actions to be taken now in the more urgent decision areas, reference can be made to an option tree such as that in Fig. 4, resequencing it if necessary so as to bring the more urgent choices to the front. Then the relative *robustness* [4] of options in the more urgent decision areas can be assessed, referring back to any progress in agreeing about preferences in the comparing mode.

Where a working group has sufficient authority to act on the proposals in a progress package without referring to other people, it can be given the more definitive name *commitment package*. Once such a package has been adopted as a basis for action, or for recommendation to others, it is a good discipline to record further details, either on the grid or elsewhere, indicating who is responsible for implementing each action, over what timescale, and by what means. For purposes of presentation to policy makers, it is now often advisable to interpret the contents of the grid in a more conventional reporting format.

As most decision makers would recognize, any action plan such as that shown in Fig. 6 involves striking a judicious compromise between commitment to early action and flexibility of future choice. Its value is both as a platform for concerted implementation and as a starting point for further cycles of decision making, in which the issues to be addressed and the people involved may change in both planned and unpredictable ways. The philosophy and methods of SCA have evolved so as to help decision makers adapt to these realities; realities that

distinguish the world of strategic or *developmental* decision making in the face of multiple uncertainties from the more orderly situations to be expected in the familiar world of OR within a well-defined corporate setting.

FURTHER READING

For further insights into the many adaptations that users of SCA have now introduced, at levels of decision making varying from governmental policy to community empowerment, reference is encouraged to the diverse accounts of applications presented in Chapter 13 of *Planning under Pressure* [2] and elsewhere [5,6].

INTRODUCTION

Vehicle routing problems are faced, in general, by companies that pickup or deliver goods to their customers by trucks. In such problems, feasible vehicle routes must be computed to fulfill given customer demands at minimum cost. Several problem variants have been studied in the literature. In this paper, we consider the vehicle routing problem with time windows (VRPTW) that can be formally stated as follows. Given an unlimited number of identical vehicles with a specified capacity, and a set of customers, each with a demand to fulfill and a delivery time interval (called a *time window*), the VRPTW consists of finding a set of routes starting and ending at a central depot such that each customer is visited exactly once within its time window, the capacity of each vehicle is respected, and the total cost (length) of the routes is minimized. The time window of a customer restricts its start of service time, but the vehicle servicing it can arrive earlier and wait until the start of the time window before beginning the service.

The VRPTW is often formulated as a set partitioning model based on the following notation. Let C be the set of customers and P the set of all feasible routes, that

is, routes starting and ending at the depot that satisfy the vehicle capacity and the visited customers' time windows. For each route $p \in P$, let c_p be its cost, a_{ip} , $i \in C$, a binary parameter equal to 1 if customer i is visited in route p , and λ_p a binary variable indicating whether or not route p is selected in the solution. The set partitioning model for the VRPTW is

$$\min \sum_{p \in P} c_p \lambda_p \quad (1)$$

$$\text{subject to: } \sum_{p \in P} a_{ip} \lambda_p = 1, \quad \forall i \in C \quad (2)$$

$$\lambda_p \text{ binary}, \quad \forall p \in P. \quad (3)$$

The objective function (1) aims at minimizing the total route cost. Set partitioning constraints (2) ensure that each customer is visited by exactly one vehicle.

Generally, this model contains a huge number of variables. To overcome this difficulty, several researchers have developed efficient branch-cut-and-price algorithms, since the early 1990s. Alternatively, Baldacci *et al.* [1] recently proposed a method that first restricts the set P to routes that have the potential to be part of an optimal solution and then solves the resulting reduced set partitioning model directly using a mixed-integer programming solver. The goal of this article is to present the main ideas behind these state-of-the-art exact methods. Additional references on these methods and alternative ones can be found in the surveys of Cordeau *et al.* [2], Kallehauge *et al.* [3], and Kallehauge *et al.* [4].

BRANCH-AND-PRICE

Branch-and-price [5–7] is the most popular methodology for solving models (1)–(3). It corresponds to a branch-and-bound algorithm where the lower bounds (LB) are computed using column generation. In this context, models (1)–(3) is called the

integer master problem (IMP) and its linear relaxation the *master problem*. Column generation is an iterative method for solving the master problem. At each iteration, it solves a so-called *restricted master problem* (RMP) and a *pricing problem*. The RMP is simply the master problem restricted to a subset of its variables λ_p . The size of this subset increases at each iteration. The RMP is thus a linear program that can be solved by the simplex algorithm. The pricing problem plays the role of determining which columns (variables) should be added to the RMP at each iteration. It aims at finding negative reduced cost columns. When no such columns exist, the current RMP solution is optimal for the master problem and the column generation method stops. Otherwise, negative reduced cost columns are added to the RMP before starting a new iteration.

For the VRPTW, each variable $\lambda_p, p \in P$, is associated with a feasible path in a network $G = (N, A)$, where N and A are the node and arc sets, respectively. The node set N contains one node for each customer $i \in C$ and two nodes, o and o' , representing the depot at the start and the end of the routes, respectively. Thus, $N = C \cup \{o, o'\}$. Each customer $i \in C$ has a demand d_i , an associated service time s_i , and a time window $[e_i, l_i]$ in which it should be visited. To simplify notation, we set $d_o = d_{o'} = s_o = s_{o'} = 0$ and $[e_o, l_o] = [e_{o'}, l_{o'}] = [0, H]$, where H is the length of the planning horizon. The arc set A is given by $A = \{(i, j) : i, j \in N, i \neq j, e_i + \tau_{ij} \leq l_j, d_i + d_j \leq D\} \setminus \{(o', o)\}$, where D is the vehicle capacity and τ_{ij} is the travel time between locations i and j plus the service time s_i at i . The last two conditions ensure that the same vehicle can visit locations i and j consecutively, according to the time and load restrictions. Denote by c_{ij} the travel cost along arc $(i, j) \in A$.

The reduced cost $\bar{c}_p$ of a variable $\lambda_p, p \in P$, is given by

$$\bar{c}_p = c_p - \sum_{i \in C} a_{ip} \pi_i = \sum_{(i, j) \in p} (c_{ij} - \pi_j) \quad (4)$$

where $\pi_j \in \mathbb{R}$ for all $j \in C$ are the dual values of Equation (2) and $\pi_{o'} = 0$. In this expression, $(i, j) \in p$ means that (i, j) is an arc of the path representing route p in G . To

determine if there exists negative reduced cost variables, one can find the shortest feasible path from o to o' in G , where the cost of each arc $(i, j) \in A$ is $\bar{c}_{ij} = c_{ij} - \pi_j$. Feasibility is enforced by resource constraints [8]. A resource is a quantity that accumulates along a path and is restricted at each node to take a value within a prespecified resource interval, called a *resource window*. For the VRPTW, the set of resources $\mathcal{R}$ contains a loading resource (*load*) to ensure that vehicle capacity is satisfied, a time resource (*time*) to respect the customer time windows, and a binary resource (*cust_i*) for each customer $i \in C$ to ensure path elementarity. The pricing problem thus corresponds to an elementary shortest path problem with resource constraints (ESPPRC). If its optimal value is negative, then the computed shortest path provides a negative reduced cost variable that can be added to the RMP (possibly with other found negative reduced cost variables). Otherwise, the column generation algorithm stops.

For solving the IMP, column generation is embedded into a branch-and-bound procedure. A classical branching rule for the VRPTW [9] is to branch on the total flow on an arc $(i, j) \in A$ (with $i \neq o$ and $j \neq o'$) which must be either 0 or 1 in any integer solution. For imposing a flow of 0 on arc (i, j) , this arc is simply removed from A in the pricing problem, while for imposing a flow of 1 on it, all arcs $(i, j') \in A$ such that $j' \neq j$ and all arcs $(i', j) \in A$ such that $i' \neq i$ are removed. For both decisions, all columns λ_p such that path p contains a removed arc are deleted from the current RMP.

FIRST-GENERATION BRANCH-AND-PRICE METHODS

2-Cycle Free Paths

Because the ESPPRC is strongly $\mathcal{NP}$ -hard [10], Desrochers *et al.* [9] proposed a branch-and-price algorithm where the pricing problem is a shortest path problem with resource constraints (SPPRC) that allows cycles (except cycles $i \rightarrow j \rightarrow i$ involving two customers $i, j \in C$, called *two-cycles*). This yields a relaxation of the master problem and possibly large integrality gaps.

The SPPRC can be solved using a labeling algorithm [8]. In such a dynamic programming method, labels represent partial paths that are extended, using so-called *extension functions*, in all feasible directions from the source node o in G . Each label L (a vector with $|\mathcal{R}| + 1$ components) stores the reduced cost of the partial path $T_{\text{rcost}}(L)$ and the current value $T_r(L)$ of each resource $r \in \mathcal{R}$. For the VRPTW, the extension along an arc (i, j) of a label L representing a partial path ending at node i proceeds as follows to create a new label L' representing a partial path ending by the arc (i, j) :

$$T_{\text{rcost}}(L') = T_{\text{rcost}}(L) + c_{ij} - \pi_j \quad (5)$$

$$T_{\text{load}}(L') = T_{\text{load}}(L) + d_j \quad (6)$$

$$T_{\text{time}}(L') = \max\{T_{\text{time}}(L) + \tau_{ij}, e_j\} \quad (7)$$

Label L' corresponds to a feasible path (that may contain cycles) if it respects the resource windows, that is, if $T_{\text{load}}(L') \in [0, D]$ and $T_{\text{time}}(L') \in [e_j, l_j]$. It is discarded if this is not the case.

To avoid enumerating all feasible paths in G , only Pareto-optimal labels (i.e., labels that are not proven to be dominated by other labels) are kept during the execution of the algorithm. When using nondecreasing extension functions as it is the case for the VRPTW, the label dominance criterion can be stated as follows:

Proposition 1 [11]. *Let L and L' be two labels representing partial paths ending at the same node. Label L dominates label L' (which can be discarded) if*

$$T_{\text{rcost}}(L) \leq T_{\text{rcost}}(L') \quad (8)$$

$$T_r(L) \leq T_r(L'), \quad \forall r \in \mathcal{R}. \quad (9)$$

When equality holds for all label components, one of the two labels must be kept.

As an extension to the idea of two-cycle free paths, Irnich and Villeneuve [12] developed a k -cycle elimination procedure for the SPPRC for arbitrary integer values of k that forbids the generation of paths containing at least one q -cycle with $q \in \{2, 3, \dots, k\}$, where a q -cycle is a subpath composed of q

arcs that start and end at the same node. This extension yields a stronger relaxation of the master problem and reduces integrality gaps.

Path Cuts

In a branch-cut-and-price method, violated valid inequalities (also called *cutting-planes* or *cuts*) are added to tighten the master problem when its computed solution is fractional. After adding cutting-planes, the master problem and the pricing problem are updated in consequence, and column generation is again performed to reoptimize the modified master problem and compute a new LB.

Kohl *et al.* [13] proposed the 2-path cuts. Such a cut forces at least two paths to visit a subset of customers when it can be proved, by solving a traveling salesman problem with time windows [14], that a single vehicle cannot serve all of them. For a subset $V \subseteq C$ of customers requiring at least two vehicles, a 2-path cut writes

$$\sum_{p \in P} \sigma_p^V \lambda_p \geq 2, \quad (10)$$

where σ_p^V is equal to the number of arcs in p entering into V . With this parameter definition, the treatment of these cuts does not pose a problem with regards to the complexity of the pricing problem because their dual values simply affect the arc costs. However, because the coefficients σ_p^V can take values greater than 1, these cuts are not as strong as they could be. Baldacci *et al.* [1] proposed a strengthened version of the 2-path cuts in which σ_p^V is equal to 1 if route p visits at least one customer in V and 0 otherwise. The downside of this improvement is that the dual value of such a cut cannot be directly transferred to the arc costs, which complicates the pricing problem. The effect is similar to that for the subset-row inequalities described in the section titled “Subset-Row Inequalities.”

RECENT BRANCH-AND-PRICE METHODS

Elementary Paths

In parallel, several researchers devised algorithms for solving the ESPPRC, allowing the generation of elementary routes and

strengthening the master problem. Feillet *et al.* [15] were the first to propose a successful labeling algorithm for the ESPPRC where one resource is required for each customer to impose elementarity. Beside the extension functions (5)–(7) for reduced cost, load, and time, the following extension functions, one per customer, are needed when extending label L along an arc (i, j) to create label L'

$$T_{\text{cust}_n}(L') = \begin{cases} T_{\text{cust}_j}(L) + 1 & \text{if } n = j \\ \max\{T_{\text{cust}_n}(L), U_n(L')\} & \text{otherwise} \end{cases} \quad \forall n \in C, \quad (11)$$

where $U_n(L')$ indicates whether or not there exist no feasible extensions of label L' reaching node $n \in C$ (n is unreachable from L). Assuming that the arc durations satisfy the triangle inequality, $U_n(L')$ is equal to 1 if $T_{\text{load}}(L') + d_n > D$ or $T_{\text{time}}(L') + \tau_{jn} > l_n$, and 0 otherwise. Label L' is discarded if $T_{\text{cust}_j}(L') > 1$.

Bidirectional labeling algorithms have been proposed by Righini and Salani [16]. These algorithms extend *forward* labels from the source node o and *backward* labels from the sink node o' before joining forward and backward labels to create feasible $o - o'$ paths. In this context, the extension of the backward labels requires backward extension functions that are different from the forward ones (Eqs 5–7 and 11). Furthermore, dominance applies only between forward labels or between backward labels.

Independently, Boland *et al.* [17] and Righini and Salani [18] proposed to initially relax the customer resources and add them iteratively until finding an elementary path. In the former paper this is referred to as *state space augmentation* and in the latter it is denoted as *decremental state space relaxation*.

Heuristic Column Generators

Solving the strongly $\mathcal{NP}$ -hard ESPPRC pricing problem to optimality at each iteration is not essential as long as negative reduced cost columns can be found. Consequently,

one can apply first a fast heuristic for the pricing problem. If it fails to produce a negative reduced cost column, then an exact labeling algorithm can be invoked. Several heuristics have been proposed in the literature. Two popular ones implement heuristic strategies in the exact labeling algorithm. The first strategy consists of eliminating arcs from network G that do not seem promising according to some criterion (for instance, their reduced cost). In the second strategy, an aggressive dominance rule is applied to eliminate a larger number of labels in the dominance procedure. For instance, one may use the standard dominance rule but considering only a (possibly empty) subset of the customer resources.

Recently, Desaulniers *et al.* [19] introduced a tabu search column generator. A tabu search method is iterative and finds at each iteration the best neighbor of the current solution (a path in the case of the ESPPRC). A neighbor is a path that is obtained from the current solution by inserting or removing a customer. To avoid cycling, the best customer insertion or removal cannot be reversed for a number of iterations: the reverse move is thus said to be tabu. To diversify the search, the tabu search method is started with different initial solutions and limited to a maximum number of iterations to perform for each initial solution. The set of initial solutions is given by the paths associated with the basic variables of the current RMP solution. All these paths are good initial candidates because they have a zero reduced cost. Using this tabu search heuristic and heuristic labeling algorithms, Desaulniers *et al.* [19] were forced to call a time-costly exact labeling algorithm only in a few column generation iterations per linear relaxation.

Subset-Row Inequalities

The subset row inequalities introduced by Jepsen *et al.* [20] are a set of valid inequalities directly defined on the master problem variables, whose dual values cannot be directly transferred to the arc costs of the pricing problem. These inequalities form a subset of the Chvátal–Gomory

(CG) rank-1 cuts for the set partitioning polytope. Given the CG multipliers $u_i^g \in [0, 1]$ for $i \in C$, a CG rank-1 cut (indexed by g) for models (1)–(3) is expressed as

$$\sum_{p \in P} \left[\sum_{i \in C} u_i^g a_{ip} \right] \lambda_p \leq \left[\sum_{i \in C} u_i^g \right]. \quad (12)$$

The subset row inequalities considered by Jepsen *et al.* [20] are obtained using a CG multiplier equal to $\frac{1}{2}$ for exactly three set partitioning constraints in Equation (2) and a zero multiplier for all the other constraints. This results in a right-hand side member $\lfloor \sum_{i \in C} u_i^g \rfloor$ of one and binary parameters $b_{gp} = \lfloor \sum_{i \in C} u_i^g a_{ip} \rfloor$ equal to 1 if and only if route p visits at least two of the three customers associated with the constraints involved in cut g . As shown by their computational results, the use of these inequalities can significantly improve the lower bound computed at the root node of the search tree. On the other hand, it increases the complexity of the ESPPRC pricing problem as each cut requires one additional resource.

Petersen *et al.* [21] extended this work and showed how any CG rank-1 cut (Eq. (12)) can be applied when using a branch-cut-and-price algorithm for solving models (1)–(3). In this case, the reduced cost of a variable λ_p also depends on the positive coefficients $\lfloor \sum_{i \in C} u_i^g a_{ip} \rfloor$ of the CG cuts and their corresponding dual values. As discussed next, the computation of these coefficients in a labeling algorithm is not straightforward because of their stepwise nature. Let $\mathcal{CG1}$ be the set of CG rank-1 cuts added to the master problem. Denote by β_g the non-positive dual variable associated with cut $g \in \mathcal{CG1}$ and by $\mathbf{u}^g$ the CG multiplier vector of size $|C|$ defining this cut. For each cut $g \in \mathcal{CG1}$, an additional resource is defined. This resource computes the current fractional part of $\sum_{i \in C} u_i^g a_{ip}$, that is, for a label L representing a partial path that visits the subset of customers $C(L)$, the value of this resource is given by $T^g(L) = \sum_{i \in C(L)} u_i^g - \lfloor \sum_{i \in C(L)} u_i^g \rfloor$. It is not restricted by resource windows. In the labeling algorithm, the forward extension of a label L along an arc $(i, j) \in A$ to create a new label L' proceeds as follows for the cut

and reduced cost components

$$T^g(L') = (T^g(L) + u_j^g) \pmod{1}, \quad \forall g \in \mathcal{CG1} \quad (13)$$

$$T_{\text{rcost}}(L') = T_{\text{rcost}}(L) + c_{ij} - \pi_j - \sum_{\substack{g \in \mathcal{CG1} \\ T^g(L) + u_j^g \geq 1}} \beta_g, \quad (14)$$

with $u_{o'}^g = 0$. The computation of the other components $T_r(L')$, $r \in \mathcal{R}$, is performed using the extension functions (6)–(7) and (11).

To discard labels in the labeling algorithm when using CG rank-1 cuts, the dominance rule of Proposition 1 can be applied considering the resource set $\mathcal{R} \cup \mathcal{CG1}$. However, this dominance criterion can be enhanced as follows:

Proposition 2 [21]. *Let L and L' be two labels representing partial paths ending at the same node. Label L dominates label L' (which can be discarded) if*

$$T_{\text{rcost}}(L) - \sum_{\substack{g \in \mathcal{CG1} \\ T^g(L) > T^g(L')}} \beta_g \leq T_{\text{rcost}}(L') \quad (15)$$

$$T_r(L) \leq T_r(L'), \quad \forall r \in \mathcal{R}. \quad (16)$$

This dominance criterion is a generalization of the one proposed by Jepsen *et al.* [20], but it is equivalent when considering only the subset row inequalities.

The separation of the CG rank-1 cuts is an $\mathcal{NP}$ -hard problem, and so is the separation of the subset row inequalities [20]. Consequently, Jepsen *et al.* [20] as well as Desaulniers *et al.* [19] and Baldacci *et al.* [1] in subsequent works considered only subset row inequalities involving exactly three constraints and used partial enumeration to find the violated ones.

SET PARTITIONING MODEL WITH ROUTE ELIMINATION

Baldacci *et al.* [1] recently proposed the most efficient exact solution method. Their algorithm combines Lagrangean relaxation and column/row generation to find a LB

on the optimal value of the IMP. The final (near optimal) dual solution is then used to eliminate all the variables whose reduced cost is larger than or equal to the gap between an upper bound (UB) on the optimal value of the IMP and LB, the LB achieved. Finally, the reduced IMP is solved with an integer programming solver.

The UB is usually computed using a fast and efficient heuristic for the VRPTW. The LB is derived from a feasible dual solution to the master problem. Baldacci *et al.* [1] find this dual solution by a column generation method that proceeds in three stages. Each stage considers as a master problem at different relaxation of the IMP. These stages are executed in sequence, the second and third ones exploiting the dual solution and the columns are generated in the previous stage. In the first two stages, the RMP is solved with a Lagrangean relaxation method based on a subgradient algorithm to avoid high degeneracy that may arise with the simplex algorithm. This dual method derives the dual variables $\pi_i, i \in C$, to price out and generate new columns.

The column generation/Lagrangean relaxation procedure $\mathcal{H}^1$ for the first stage generates *ng*-routes. An *ng*-route is obtained by adding arc (o, i) to an *ng*-path (NG, t, i) defined as a path (not necessarily elementary) starting from node $i \in C$ at time $t \in [e_i, l_i]$, visiting at least once each customer in a subset $NG \subseteq C$ within its time window, and ending at the depot at time H . In this procedure, the pricing problem generates routes with a forward labeling algorithm. The second-stage procedure $\mathcal{H}^2$ generates elementary routes satisfying both time and capacity constraints. These routes are also generated by a forward labeling algorithm that uses *ng*-paths to calculate LBs on the reduced costs of the completions of the partial elementary paths represented by the forward labels. If the calculated LB for a label is greater than 0, then this label can be discarded. The third-stage procedure $\mathcal{H}^3$ is a classical column/row generation algorithm based on the simplex algorithm to solve the master problem strengthened by the subset row inequalities involving exactly three customers. In this

procedure, the elementary routes are generated using a bidirectional labeling algorithm. As above, label fathoming using *ng*-paths (and their symmetric counterparts) is also used. Furthermore, a route can be fathomed if its reduced cost with respect to the feasible dual solution found by $\mathcal{H}^2$ exceeds the difference between *UB* and the LB achieved by $\mathcal{H}^2$. At the end of procedure $\mathcal{H}^3$, we have on hand a LB *LB* and dual variable values $\pi_i, i \in C$, associated with the set partitioning constraints, and $\beta_g, g \in SR3$, associated with the generated subset row inequalities, where *SR3* denote the subset of those cuts saturated in the solution of the final RMP.

After computing this dual solution, the proposed algorithm enumerates, using a specialized dynamic programming algorithm, all routes $p \in P$, whose reduced cost

$$\bar{c}_p = c_p - \sum_{i \in C} a_{ip} \pi_i - \sum_{g \in SR3} b_{gp} \beta_g, \quad (17)$$

satisfies $\bar{c}_p < UB - LB$, before constructing a reduced set partitioning type models (1)–(3) augmented by the subset row inequalities in *SR3*. The resulting reduced problem is then solved by a commercial branch-and-cut solver. The effectiveness of this method highly depends on the quality of the computed dual solution $\pi_i, i \in C$ and $\beta_g, g \in SR3$. Better quality solutions yield smaller reduced problems that are, in general, easier to solve.

This algorithm was tested on the Solomon's benchmark instances that are available at <http://web.cba.neu.edu/~msolomon/problems.htm>. This benchmark set comprises 168 instances that are divided into three groups of 56 instances involving 25, 50, and 100 customers, respectively. Each group contains six instance classes (C1, RC1, R1, C2, RC2, and R2) differing by the geographical distribution of the customers or the average width of the time windows. The algorithm of Baldacci *et al.* [1] was able to solve to optimality 167 of these 168 instances, outperforming all other existing exact algorithms. On average, it was five to six (respectively seven to eight) times faster than the branch-cut-and-price algorithm of Jepsen *et al.* [20] (respectively Ref. 19) on the instances solved by both algorithms. The

only instance that remains open is the R208 instance with 100 customers.

CONCLUSIONS AND FUTURE RESEARCH DIRECTIONS

The first attempt to solve the VRPTW by column generation dates back two decades. A lot has been done since that time but still, one test-instance from the Solomon's benchmark set fails to be solved and its most difficult instances have only been solved in the last few years. Advances have been made by the combination of various techniques: bidirectional dynamic programming labeling algorithms to compute elementary routes, various cutting-planes to strengthen the LBs, new label dominance and fathoming rules to accelerate the labeling algorithms, Lagrangean relaxation methods to avoid degeneracy of the master problem, heuristic column generators to speed up the overall process, and so on.

Future research will certainly concern the acceleration of these techniques. In particular, three issues need to be investigated. First, efficient algorithms for solving the ESPPRC are still missing. Branch-and-cut and decomposition-based algorithms seem interesting alternatives to dynamic programming. Arc elimination to reduce the size of the pricing problem should also be considered. Second, all state-of-the-art algorithms would benefit from new types of cutting-planes that can substantially improve the LBs. Finally, good optimal dual value estimates could be exploited in a dual variable stabilization procedure to reduce the number of column generation iterations and speed up the overall solution process.

THE WEIGHTED MOVING AVERAGE TECHNIQUE

MARCUS B. PERRY

Department of Information Systems,
Statistics and Management Science,
The University of Alabama,
Tuscaloosa, Alabama

INTRODUCTION

The w -term moving average (MA) is most often applied to time series data as a means to smooth out seasonal variation or irregular fluctuations in the data, permitting the analyst to more easily identify the structural patterns. It is also used as a means for computing short-term forecasts of time series. Its application in practice is widespread across many disciplines. For example, in an engineering application, one might use the MA in efforts to control the quality of a product or process. Further, in a business application, the MA might be used to forecast future sales demand or employee turnover. Depending on the application, different types of MAs can be computed (e.g., simple, weighted, and cumulative). Further, MAs can be centered by placing each w -term average in the middle of its corresponding w -length time interval. If w is odd, then by this placement, the MA is centered. On the other hand, if w is even, a 2-term moving average is required to center the original MA. Centered MAs are more typical when the primary objective of the analysis is seasonal adjustment of the data.

In this tutorial, emphasis is placed on the *weighted* moving average (WMA), where each w -term average is placed at the upper bound of its corresponding w -length time interval. In particular, consider the n -length time series $\{x_i\}$, then its w -term WMA is defined as

$$z_i = \sum_{j=i-w+1}^i \omega_j x_j, \quad (1)$$

for $i \in [w, w+1, \dots, n]$, where the ω_j 's are weights and the x_j 's are a time sequence of (possibly autocorrelated) random variables. Notice that the number of observations in the series $\{z_i\}$ is reduced to $n - w + 1$; that is, $w - 1$ terms are lost in the WMA. As noted by one of the reviewers, the right-hand side of Equation (1) defines a convex hull for the data points, and thus z_i is a point in the convex hull of data up to the present. The WMA defined in Equation (1) is useful for computing one-step-ahead (i.e., short-term) forecasts or predictions. Further, it lends nicely to the development of process monitoring algorithms useful in, say, statistical quality control applications.

The WMA in Equation (1) can be written in vector notation as

$$\begin{aligned} z_i &= (\omega_{i-w+1}, \omega_{i-w+2}, \dots, \omega_i) \begin{pmatrix} x_{i-w+1} \\ x_{i-w+2} \\ \vdots \\ x_i \end{pmatrix} \\ &= \omega_i' \mathbf{x}_i, \end{aligned} \quad (2)$$

where ω_i and $\mathbf{x}_i$ are both $w \times 1$ and $\sum_{k=1}^w \omega_{i-w+k} = 1$. If the ω_i 's are constant for all i , then z_i can be written as

$$z_i = (\omega_1, \omega_2, \dots, \omega_w) \begin{pmatrix} x_{i-w+1} \\ x_{i-w+2} \\ \vdots \\ x_i \end{pmatrix} = \omega' \mathbf{x}_i, \quad (3)$$

where $\sum_{k=1}^w \omega_k = 1$, and whereby applying larger weights to the more recent observations yields the additional constraint $\omega_1 \leq \omega_2 \leq \dots \leq \omega_w$. Consider the special case where $\omega_k = w^{-1}$ for all k , then this produces the w -term *simple* MA given by

$$z_i = w^{-1} \sum_{j=i-w+1}^i x_j, \quad (4)$$

which is just the arithmetic average of the w terms.

Figure 1. Examples of weighted moving averages.

To illustrate the computation of a w -term simple MA, consider $w = 3$ and the series

$$\{x_i\} = [1.3 \quad 2.5 \quad 4.1 \quad 2.9 \quad 1.6].$$

Since $n = 5$ and $w = 3$, the new series $\{z_i\}$ will contain three observations (i.e., z_3, z_4, z_5) computed, respectively, as

$$z_3 = (1.3 + 2.5 + 4.1)/3 = 2.63$$

$$z_4 = (2.5 + 4.1 + 2.9)/3 = 3.17$$

$$z_5 = (4.1 + 2.9 + 1.6)/3 = 2.87,$$

and thus the new series $\{z_i\}$ (for $i = 3, 4, 5$) is given as¹

$$\{z_i\} = [\cdot \quad \cdot \quad 2.63 \quad 3.17 \quad 2.87].$$

¹Note that the centered MA for this case is given as $\{z_i\} = [\cdot \quad 2.63 \quad 3.17 \quad 2.87 \quad \cdot]$.

To illustrate further, consider the scatter plots of $n = 50$ independently generated standard normal random deviates shown in Fig. 1. For each plot, the horizontal axis denotes time and the vertical axis denotes the observed value of X at time i . The solid line in Fig. 1a shows a 2-term WMA with $\omega_1 = 0.25$ and $\omega_2 = 0.75$. Similarly, the solid line in Fig. 1b shows a 3-term WMA with $\omega_1 = 0.15$, $\omega_2 = 0.25$, and $\omega_3 = 0.60$. A 4-term WMA with $\omega_1 = 0.10$, $\omega_2 = 0.15$, $\omega_3 = 0.25$, and $\omega_4 = 0.50$ is given in Fig. 1c, while a 5-term WMA with $\omega_1 = 0.10$, $\omega_2 = 0.15$, $\omega_3 = 0.20$, $\omega_4 = 0.25$, and $\omega_5 = 0.30$ is shown in Fig. 1d.

It seems apparent from Fig. 1 that as the number of terms in the MA increases, so does the amount by which $\{x_i\}$ is smoothed. The implication is that the variance of z_i reduces with the addition of more terms; however, at the expense of bias. This is quite

intuitive and in-line with the well-known variance-bias trade-off. This is discussed in more detail in a later section.

In the next section several properties of z_i are evaluated, including the mean, variance, and the variance of the one-step-ahead forecast errors. In subsequent sections, some common applications of the WMA in practice are discussed.

PROPERTIES

Let $\mathbf{x}_i = (x_{i-w+1}, x_{i-w+2}, \dots, x_i)'$ be a $w \times 1$ random vector with mean μ_i and finite autocovariance matrix $\Sigma = \sigma_x^2 \mathbf{R}$, where $\mathbf{R}$ denotes the $w \times w$ autocorrelation matrix of $\mathbf{x}_i$ and σ_x^2 denotes the variance of the original process $\{x_i\}$. Note the special case of the uncorrelated process when $\mathbf{R} = \mathbf{I}$. Note further that μ_i is $w \times 1$ and is given explicitly as²

$$\mu_i = (\mu_{i-w+1} \quad \mu_{i-w+2} \quad \cdots \quad \mu_i)' \quad (5)$$

and $\mathbf{R}$ has the form³

$$\mathbf{R} = \begin{pmatrix} 1 & \rho_1 & \rho_2 & \cdots & \rho_{w-1} \\ \rho_{-1} & 1 & \rho_1 & \cdots & \rho_{w-2} \\ \rho_{-2} & \rho_{-1} & 1 & \cdots & \rho_{w-3} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \rho_{-w+1} & \rho_{-w+2} & \rho_{-w+3} & \cdots & 1 \end{pmatrix}, \quad (6)$$

where $\rho_m = \rho_{-m}$ denotes the lag m autocorrelation of $\mathbf{x}_i$.

Applying the expectation operator to z_i we obtain

$$E(z_i) = \omega' \mu_i \quad (7)$$

and by applying the variance operator to z_i we find

$$\sigma_z^2 = \sigma_x^2 (\omega' \mathbf{R} \omega), \quad (8)$$

where for uncorrelated processes

$$\sigma_z^2 = \sigma_x^2 \sum_{k=1}^w \omega_k^2. \quad (9)$$

Suppose that one uses z_i to forecast x_{i+1} , then applying the variance operator to $z_i - x_{i+1}$ yields the variance of the one-step-ahead forecast errors (i.e., prediction errors), or

$$\sigma_{\text{pred}}^2 = \sigma_x^2 \left(1 + \omega' \mathbf{R} \omega - 2 \sum_{k=1}^w \omega_k \rho_{w-k+1} \right), \quad (10)$$

where for the uncorrelated process $\rho_m = 0$ ($m > 0$) and Equation (10) reduces to

$$\sigma_{\text{pred}}^2 = \sigma_x^2 + \sigma_z^2, \quad (11)$$

which is the sum of the variances of the original process $\{x_i\}$ and the WMA process $\{z_i\}$.

In much of what follows, references will be made to different time series models for autocorrelated processes. These models consist of the class of stationary and invertible autoregressive moving average (ARMA) models discussed in Box *et al.* [1]. Additional references to these models include Abraham and Ledolter [2] and Pankratz [3]. The notation $\text{ARMA}(p, q)$ is often used to denote the ARMA model of order p and q ; that is, we have a model with p autoregressive terms and q moving average terms. The notation is shortened further when the model contains only autoregressive or moving average terms. That is, a model containing p autoregressive terms and no moving average terms is denoted by $\text{AR}(p)$. Similarly, a model containing q moving average terms and no autoregressive terms is denoted by $\text{MA}(q)$. This notation will be used in subsequent sections of this tutorial.

3-Term WMA Applied to AR(1) Process

Suppose that the process under consideration is well characterized by a first-order autoregressive model, or

$$x_i = \mu + \phi(x_{i-1} - \mu) + \epsilon_i. \quad (12)$$

²Note that the original process $\{x_i\}$ need not be mean stationary.

³For covariance stationary processes, $\text{Var}(\mathbf{x}_i) = \sigma_x^2 \mathbf{R}$ for all $i \Rightarrow$ covariance is only a function of lag.

Suppose further that $\sigma_\epsilon^2 = 1$ and $\phi = 0.50$, then it can be shown that $\sigma_x^2 = (1 - \phi^2)^{-1} = 1.3333$. Also, for a 3-term WMA, we have the correlation matrix

$$\mathbf{R} = \begin{pmatrix} 1.00 & 0.50 & 0.25 \\ 0.50 & 1.00 & 0.50 \\ 0.25 & 0.50 & 1.00 \end{pmatrix} \quad (13)$$

so that for $\omega = [0.15, 0.25, 0.60]'$ we obtain for all i

$$E(z_i) = \mu \quad (14)$$

$$\sigma_z^2 = 0.9033, \quad (15)$$

and the variance of the one-step-ahead forecast errors obtained from Equation (10) is given by⁴

$$\sigma_{\text{pred}}^2 = 1.2200. \quad (16)$$

To put this example into practical context, suppose the process in Equation (12) well models a sales demand process and one is interested in monitoring for changes in mean sales demand over time. To accomplish this, one can plot z_i for each i and compare to the limits $\mu_0 \pm L\sigma_z$, where μ_0 is some hypothesized *expected* value of sales demand, $\sigma_z = \sqrt{0.9033}$ and L is a constant expressed in standard deviation units.⁵ If any point exceeds these limits, one can conclude that the mean sales demand has changed, and thus plans might be devised at this point to increase or decrease production for the next period.

5-Term WMA Applied to ARMA(1,1) Process

Suppose now that the process under consideration is well modeled by the ARMA(1,1) model with $\phi = 0.75$ and $\theta = -0.35$, or

$$x_i = \mu + 0.75(x_{i-1} - \mu) + 0.35\epsilon_{i-1} + \epsilon_i. \quad (17)$$

Suppose again that $\sigma_\epsilon^2 = 1$, then it can be shown that

$$\sigma_x^2 = \frac{1 + \theta^2 - 2\phi\theta}{(1 - \phi^2)} = 3.7657 \quad (18)$$

and for a 5-term WMA we have the correlation matrix

$$\mathbf{R} = \begin{pmatrix} 1.0000 & 0.8429 & 0.6322 & 0.4742 & 0.3556 \\ 0.8429 & 1.0000 & 0.8429 & 0.6322 & 0.4742 \\ 0.6322 & 0.8429 & 1.0000 & 0.8429 & 0.6322 \\ 0.4742 & 0.6322 & 0.8429 & 1.0000 & 0.8429 \\ 0.3556 & 0.4742 & 0.6322 & 0.8429 & 1.0000 \end{pmatrix}, \quad (19)$$

so that for $\omega = [0.10, 0.15, 0.20, 0.25, 0.30]'$ we obtain for all i

$$E(z_i) = \mu \quad (20)$$

$$\sigma_z^2 = 2.8163 \quad (21)$$

and the variance of the one-step-ahead forecast errors obtained from Equation (10) is given by

$$\sigma_{\text{pred}}^2 = 2.1703. \quad (22)$$

Notice that $\sigma_{\text{pred}}^2 < \sigma_z^2$ for this process,⁶ and thus for our sales demand monitoring example described above, one might consider monitoring the one-step-ahead forecasts $x_i - z_{i-1}$ in place of z_i to gain a reduction in variance of the charting statistic. That is, the quantity $x_i - z_{i-1}$ would be computed and compared to the limits $\pm L\sqrt{2.1703}$.

Figure 2 shows a single realization of the ARMA(0.75, -0.35) process with two 5-term WMAs superimposed. The WMA shown as the solid line has weights $\omega_1 = 0.10$, $\omega_2 = 0.15$, $\omega_3 = 0.20$, $\omega_4 = 0.25$, and $\omega_5 = 0.30$, while the WMA shown as the dotted line has weights $\omega_k = 0.20$ for $k = 1, 2, \dots, 5$, which is the 5-term *simple* MA. Note that for this

⁴Note also that $E(z_i - x_{i+1}) = 0$.

⁵ L is often chosen on the basis of an acceptable type-I error.

⁶There is more uncertainty associated with $\{z_i\}$ than with $\{x_i - z_{i-1}\}$ due to strong positive autocorrelation. In general, $\sigma_{\text{pred}}^2 < \sigma_z^2$ when $\sum_{k=1}^w \omega_k \rho_{w-k+1} > \frac{1}{2}$.

Figure 2. Single realization of ARMA(0.75, -0.35) process with two 5-term WMAs.

Figure 3. Monthly rose wine sales data with a 5-term simple MA and a 5-term WMA superimposed. Total number of observations is $n = 173$ and $w = 4$ terms are lost.

realization, the two MAs track closely, with only marginal differences. In the next section some of the more common applications of the WMA in practice are discussed.

APPLICATIONS OF THE WEIGHTED MOVING AVERAGE

One of the most common applications of the WMA is generating one-step-ahead forecasts of time series. For example, consider Fig. 3, where monthly Australian sales

of rose wine is plotted over 173 months from approximately January 1980 to April 1995. The data and its original source can be obtained from the Time Series Data Library.⁷ Superimposed on this data are a 5-term WMA⁸ (solid line) and a 5-term simple MA (dotted line). Notice that this

⁷The Time Series Data Library is accessible at <http://www.robjhyndman.com/TSDL/>.

⁸Note that $\omega = [0.10, 0.15, 0.20, 0.25, 0.30]$ for this application.

Figure 4. Weekly closing price of AT&T common shares. Total number of observations is $n = 51$ and $w = 4$ terms are lost.

process has some significant seasonal effects evidenced by the overall trend and cyclical-type fluctuations in the MAs. The forecast for x_{174} is then given by $\hat{x}_{174} = z_{173}$, which for the simple MA and WMA cases we have $\hat{x}_{174} = 39.80$ and $\hat{x}_{174} = 41.85$, respectively. The actual sales in the 174th month was $x_{174} = 45.00$, thus, for this realization, the WMA provides a more accurate forecast than that provided by the simple MA.

Consider a second example taken from Pankrats [3] involving the weekly closing price of AT&T common shares. The data set consists of $n = 52$ observations taken over each week in 1979. Figure 4 shows the data up through the 51st week along with 5-term simple and WMAs superimposed. If the WMA is used to forecast closing price in the 52nd week, then $\hat{x}_{52} = 53.05$, and the forecast using the simple MA is $\hat{x}_{52} = 53.25$. The actual closing price at week 52 was $x_{52} = 52.25$. Thus, again we see that for this realization, applying higher weights to more recent observations provides a more accurate forecast (albeit marginal in this case).

We can improve on the *accuracy* of the forecast by reducing the number of terms in the MA; however, this will result in an increase in σ_z^2 (i.e., a decrease in precision). For example, Fig. 5 shows three different WMAs with $w = 2, 3$, and 5, respectively.

Notice that the 2-term WMA forecast for x_{52} is $\hat{x}_{52} = 52.19$, which is very close to the actual value of $x_{52} = 52.25$. However, the amount by which z_i fluctuates when $w = 2$ is noticeably greater if, say, $w = 5$.

This reduction in σ_z^2 as w increases is easily shown for the uncorrelated process. If the observations are uncorrelated, then Equation (8) can be written as

$$\sigma_z^2 = \sigma_x^2(\omega' \omega) = \sigma_x^2 \sum_{k=1}^w \omega_k^2 \quad (23)$$

and for the simple MA $\omega_k = w^{-1}$ for all $k = 1, 2, \dots, w$ and

$$\sigma_z^2 = \frac{\sigma_x^2}{w} \quad (24)$$

so that as $w \rightarrow \infty$ then $\sigma_z^2 \rightarrow 0$.

The above examples demonstrate how the WMA can be applied to generate one-step-ahead forecasts of a time series. Typically, in these applications, the WMA is useful when the forecast horizon is short-term [4]. Other methods are more frequently used for computing mid-to-long-term forecasts.

Another common application of the WMA is in the area of quality control. In particular, the WMA is often used for monitoring critical process quality characteristics over time

Figure 5. Three different WMAs of weekly closing price of AT&T common shares. Total number of observations is $n = 51$.

Figure 6. 5-term *two-sigma* WMA control chart applied to simulated ARMA(0.95, -0.65) process. Note the control chart signaled on the 77th observation, suggesting a decrease in the expected yield of the process.

[5,6]. For example, suppose that the process under consideration is a chemical process where the output being monitored is yield. Suppose further that the process is highly autocorrelated and its *expected* behavior is well modeled by the ARMA(0.95, -0.65) process, or

$$x_i = 500 + 0.95(x_{i-1} - 500) + 0.65\epsilon_{i-1} + \epsilon_i \quad (25)$$

for all i with $\sigma_\epsilon^2 = 15.00$. Thus, $\sigma_x^2 = 408.8462$ and for a 5-term WMA,⁹ we find

$$\sigma_z^2 = 387.0393. \quad (26)$$

Suppose it is of interest to detect changes in the expected yield of the process, say from $\mu_i = 500$ to $\mu_i = \mu_1$, where $\mu_1 \neq 500$.

⁹ $\omega' = [0.10, 0.15, 0.20, 0.25, 0, 30]$.

The WMA can be used as a basis for constructing a *control chart*.¹⁰ That is, we could compute z_i (at each time i) and compare to the upper and lower control limits $500 \pm L\sqrt{\sigma_z^2} = 500 \pm 19.6733L$, where L is a constant. If z_i exceeds either of these limits, then a signal is issued and a special-cause investigation is initiated in efforts to uncover the underlying cause of the process change. The constant L is expressed in standard deviation units and is set to achieve an acceptable false alarm rate. If we set $L = 2$, then Fig. 6 shows a *two-sigma* WMA control chart applied to a simulated realization of the ARMA(0.95, -0.65) process with $\sigma_\epsilon^2 = 15.00$. Initially, the process was simulated so that $\mu_i = 500$ for all $i = 1, 2, \dots, 50$. However, for $i > 50$ the process was simulated so that $\mu_i = 485$. Notice that $z_{77} < \text{LCL}$, which suggest that the expected yield of the process has decreased.¹¹ Since high yield is desirable, production would cease at this point and a special-cause search is initiated. When using $\{z_i\}$ as a control charting statistics, smaller shifts in the process mean are guarded against most effectively with larger w ; however, at the expense of quick response to large shifts [7]. Therefore, if the detection of smaller-sized shifts is of interest, w should be set sufficiently large. For larger-sized shifts, w should be set sufficiently small. Sparks [5] provides further discussion on strategies for choosing ω and w when using the WMA for process monitoring.

The above illustrations are not the only applications of the WMA; however, they are common applications of the WMA in the management science and quality engineering disciplines. In general, application of the WMA is widespread throughout several

disciplines, including health, finance, criminal justice, sports, industry, demography, and many more.

SUMMARY

In this tutorial, the WMA was discussed. As previously noted, the WMA is often used for smoothing irregular fluctuations (i.e., noise) in a time series to permit the data analyst to better reveal the trend-cycle patterns over time. Additionally, the WMA is frequently used to compute short-term forecasts of time series (e.g., sale and stocks). Some common applications of the WMA in the management science and quality engineering disciplines were also discussed. Further, the expected value, variance, and one-step-ahead prediction variance of the WMA were evaluated. For more information on the WMA and its application, see Bowerman *et al.* [8], Abraham and Ledolter [2], and Makridakis *et al.* [9].

¹⁰Control charts are often used to distinguish between common-cause and special-cause process variability. Common-cause variation is deemed “unavoidable” and special-cause variation “avoidable.”

¹¹Note that the control chart required $77 - 50 = 27$ additional samples after the change in order to detect the simulated decrease.

THEORY OF MARTINGALES

YINGDONG LU

New York

INTRODUCTION

Suppose that we have a probability space $(\Omega, \mathcal{F}, P)$, a filtration $\{\mathcal{F}_n\}_{n=1}^{\infty}$ is defined as a family of σ -algebras $\mathcal{F}_n \subset \mathcal{F}$ satisfying $\mathcal{F}_n \subseteq \mathcal{F}_{n+1}$ for any $n = 1, 2, \dots$. For many practical problems, the filtration models the amount of information available to the decision makers.

Definition 1 A sequence of random variables X_n is a martingale with respect to the filtration $\{\mathcal{F}_n\}$, if it satisfies,

1. $X_n \in \mathcal{F}_n$;
2. $E|X_n| < \infty$;
3. $E[X_{n+1}|\mathcal{F}_n] = X_n$.

In the following, the filtration in each martingale is usually quite obvious; therefore, we omit mentioning the filtration unless it is necessary. While the focus of the authors' discussion is discrete-time processes in this article, most of the results have their continuous counterparts, and we have a brief discussion in one of the following sections. More detailed discussion on the basic concepts of both discrete-time and **Continuous-Time Martingales** can be found in the two articles of **Discrete-Time Martingales** and **Continuous-Time Martingales**.

Martingales, as an important class of stochastic processes, play an important role in modern probability theory. This important role is clearly manifested in such developments as the analysis of random walk, the martingale problem for Markov

processes, and the martingale methods in the construction of stochastic integration and understanding of diffusion processes. Meanwhile, being a powerful tool characterizing correlation, martingale methods and techniques are widely applied in mathematics, science, and engineering. For many problems in operations research and management science, martingales serve as an essential modeling and analytic tool for quantitatively characterizing statistical dependence that often rises when uncertainty and risk are involved. A typical example can be found in the martingale model of forecast evolution, a popular forecast update scheme, proposed in Refs 1 and 2. Finally, for such fields as mathematical finance, actuarial science, and stochastic optimal control, martingale is a necessary part of their foundations.

Like several other important probabilistic concepts, see, for example, Ref. 3, martingale finds its root in gambling. Intuitively, it characterizes the following fact, in a fair game, the knowledge of the past events will not enable the players to predict the future outcomes. This makes martingale a perfect building block in modeling decision making, which is the focus of applications in operations research and management science. Many applications in these areas often require deep understanding of the martingale model and analysis. In this article, following the two articles **Discrete-Time Martingales** and **Continuous-Time Martingales**, we discuss some advanced concepts and analysis in the theory of martingales.

The following concrete examples demonstrate that martingales are tied to some basic objects in probability and statistics, which are instrumental in modeling and analysis in operations research and management science.

Example 1 Summation of independent random variables can be studied as a martingale. More specifically, if $Y_1, Y_2, \dots$

are independent random variables satisfying $E[Y_i] = 0$, and $\text{Var}[Y_i] = \sigma_i^2$, it is easy to verify that $X_n = Y_1 + Y_2 + \dots + Y_n$ is a martingale. Meanwhile, we have, $E[(\sum_{i=1}^{n+1} Y_i)^2 | Y_1, Y_2, \dots, Y_n] = (\sum_{i=1}^n Y_i)^2 + \sigma_{n+1}^2$, therefore, $Z_n = (\sum_{i=1}^n Y_i)^2 - \sum_{i=1}^n \sigma_i^2$ is also a martingale.

Example 2 Let $Y_1, Y_2, \dots$ be independent and identically distributed random variables with finite moment generating function, define $\phi(\lambda) = E[\exp(\lambda Y_1)]$, for some $\lambda > 0$, then,

$$X_n = \phi(\lambda)^{-n} \exp\left(\lambda \sum_{i=1}^n Y_i\right)$$

is a martingale, and it is also known as the *Wald's martingale*. To see this, we have,

$$\begin{aligned} E[X_{n+1} | Y_1, Y_2, \dots, Y_n] &= \phi(\lambda)^{-(n+1)} E\left[\exp\left(\lambda \sum_{i=1}^{n+1} Y_i\right) \middle| Y_1, Y_2, \dots, Y_n\right] \\ &= \phi(\lambda)^{-(n+1)} \exp\left(\lambda \sum_{i=1}^n Y_i\right) E[\exp(\lambda Y_{n+1})] \\ &= \phi(\lambda)^{-n} \exp\left(\lambda \sum_{i=1}^n Y_i\right). \end{aligned}$$

Example 3 Suppose that $f(\cdot)$ is the density function of Y_i and $g(\cdot)$ is another probability density function, then,

$$X_n = \frac{g(Y_1)g(Y_2) \dots g(Y_n)}{f(Y_1)f(Y_2) \dots f(Y_n)}$$

is a martingale, which has its root in the likelihood ratio test. To verify this, we see,

$$\begin{aligned} E[X_{n+1} | Y_1, Y_2, \dots, Y_n] &= E\left[\frac{g(Y_1)g(Y_2) \dots g(Y_n)g(Y_{n+1})}{f(Y_1)f(Y_2) \dots f(Y_n)f(Y_{n+1})} \middle| Y_1, Y_2, \dots, Y_n\right] \\ &= \frac{g(Y_1)g(Y_2) \dots g(Y_n)}{f(Y_1)f(Y_2) \dots f(Y_n)} E\left[\frac{g(Y_{n+1})}{f(Y_{n+1})}\right] \\ &= X_n \int \frac{g(z)}{f(z)} f(z) dz = X_n. \end{aligned}$$

Example 4 Martingale is also a powerful tool to study Markov chains. For example, suppose that Y_n is a Markov chain governed by transition probability matrix $P = (P_{ij})$, then for any function $f: \mathbb{Z} \rightarrow \mathbb{R}$ that satisfies $af(i) = \sum_j P_{ij}f(j)$ for some $a > 0$, it is well known that $X_n = a^{-n}f(Y_n)$ is a martingale, as

$$\begin{aligned} E[a^{-(n+1)}f(Y_{n+1}) | Y_1, \dots, Y_n] &= E[a^{-(n+1)}f(Y_{n+1}) | Y_n] = a^{-(n+1)} \sum_j P_{Y_n j} f(j) \\ &= a^{-n}f(Y_n) = X_n. \end{aligned}$$

The condition, $af(i) = \sum_j P_{ij}f(j)$, is certainly satisfied by the eigenvector of the operator P .

Example 5 For any random variable X with $E[|X|] < \infty$, and $\mathcal{F}_n$ a filtration defined on the same probability space, define $X_n = E[X | \mathcal{F}_n]$, all the three conditions in the definition are satisfied, X_n is a martingale. It is known as the *Doob's martingale*, or the *Levy's martingale*, and a central model in stochastic approximation methods.

In many applications, condition 3 in the definition can only be satisfied in inequality form. This leads to the following pair of concepts that are closely related to martingale, submartingale, and supermartingale. When the equality in condition 3 is relaxed to $\geq$ ($\leq$) the sequence is called *submartingale* (*supermartingale*). There is a symmetry between the submartingale and supermartingale, so from now on, we just present the results for submartingale. Unless we specifically point out, the reader should know that there is a counterpart for supermartingale. The fundamental relationship between the martingale and the submartingale is best characterized in the following decomposition theorem.

Theorem 1 (*Doob's decomposition theorem*) For any submartingale Y_n , there is always a martingale X_n , and a predictable and increasing process A_n , such that $Y_n = X_n + A_n$, for any $n = 1, 2, \dots$

In the following sections, we review some basic concepts and results for martingales. In the section titled “Martingale Inequalities,” we discuss several martingale inequalities. In the section titled “Martingale Limit Theorem,” we review basic martingale convergence theorem, including law of large number and central limit theorem in general form. In the section titled “Optional Stopping Theorem,” the important topic of optional stopping is reviewed. In the section titled “Martingale with Continuous Parameters and Brownian Motion,” we discuss martingales with continuous parameter, especially Brownian motion. In the section titled “Historical Notes and Further Readings,” we review some historical development and provide some further readings.

MARTINGALE INEQUALITIES

Four types of inequalities are discussed in this section: (i) (Doob’s) maximal inequality, (ii) Burkholder’s inequality, (iii) decoupling inequalities, and (iv) concentration inequalities.

Maximal Inequalities

Doob’s maximal inequality indicates that the expected maximum of a submartingale can be controlled by the expected submartingale itself. We like to point out that maximal inequalities are extensions of the Kolmogorov’s inequality for independent and identically distributed random variables, see, for example, Ref. 4. They can be proved in the same manner. The following lemma is a key in establishing the maximal inequality, and we include the proof here for two reasons: first, we want to point out its root in the Kolmogorov’s inequality. Second, this is a typical argument in establishing many results in martingale theory, namely, identifying where the event happens and analyzing the event locally.

Lemma 1 *For a submartingale X_n , for any constant $C > 0$, we have,*

$$\mathbb{CP} \left[\sup_{1 \leq k \leq n} X_k \geq C \right] \leq \mathbb{E} \left[X_n \mathbf{1} \left\{ \sup_{1 \leq k \leq n} X_k > C \right\} \right].$$

Proof. The event under study is $\{\sup_{1 \leq k \leq n} X_k > C\}$. The key argument is to identify when the supremum is achieved. For this reason, define $A_i = \{X_i > C, \max_{j < i} X_j \leq C\}$. It is easy to see that A_i and A_j have no overlap, for any $i \neq j$, and their union recovers the event $\{\sup_{1 \leq k \leq n} X_k > C\}$. In other words, the event $\{\sup_{1 \leq k \leq n} X_k > C\}$ can be decomposed to the union of disjoint sets A_i . Hence, we have the following identity for its probability,

$$\mathbb{CP} \left[\sup_{1 \leq k \leq n} X_k \geq C \right] = C \sum_{i=1}^n \mathbb{P}[A_i].$$

Now, our problem has been reduced to estimate the probability of the smaller sets A_i , $i = 1, 2, \dots, n$.

From the way A_i is defined, we immediately have,

$$\mathbb{CP}[A_i] \leq \mathbb{E}[X_i \mathbf{1}(A_i)].$$

The definition of submartingale then implies,

$$\mathbb{E}[X_i \mathbf{1}(A_i)] \leq \mathbb{E}[\mathbb{E}[X_n | \mathcal{F}_i] \mathbf{1}(A_i)].$$

Meanwhile, as A_i is measurable with respect to $\mathcal{F}_i$, we have,

$$\mathbb{E}[\mathbb{E}[X_n | \mathcal{F}_i] \mathbf{1}(A_i)] = \mathbb{E}[\mathbb{E}[X_n \mathbf{1}(A_i) | \mathcal{F}_i]].$$

The right-hand side is, of course, equal to $\mathbb{E}[X_n \mathbf{1}(A_i)]$. The desired inequality thus follows when all the terms are summed up. $\square$

The following theorem is obtained from Lemma 1 through integration.

Theorem 2 *(Doob’s inequality) For a martingale, X_n , and any $p > 1$, we have,*

$$\|X_n\|_p \leq \left\| \sup_{1 \leq k \leq n} X_k \right\|_p \leq \frac{p}{p-1} \|X_n\|_p,$$

where $\mathbb{E}\|X\|_p = (\mathbb{E}[|X|^p])^{1/p}$.

The maximum inequality and its variations provide a vehicle to estimate the magnitude of the maximum of the martingale by its terminal value, hence, play important

roles in the analysis of random combinatorial algorithms and network scheduling, for some recent applications in these areas, see, for example, Refs 5 and 6.

Burkholder's Inequality

For a martingale X_n , the process $D_n = X_n - X_{n-1}$ is known as the *martingale difference sequence*, and $\sum_{i=1}^n D_i^2$ is known as the *quadratic variation process*, which is an important indicator of the volatility of the martingale X_n . Burkholder's inequality, sometimes is also called the *square function inequality*, establishes a fundamental relationship between the growth of martingale and that of the quadratic variation.

Theorem 3 *For any $p > 1$, there exist positive constants c and C such that the following inequality holds for martingale $X_n = \sum_{i=1}^n D_i$,*

$$\begin{aligned} c \left(\mathbb{E} \left[\sum_{i=1}^n D_i^2 \right] \right)^{p/2} \\ \leq \mathbb{E} [|X_n|^p] \leq C \left(\mathbb{E} \left[\sum_{i=1}^n D_i^2 \right] \right)^{p/2}. \end{aligned}$$

This fundamental relationship between the martingale and the square function of the martingale difference sequence is also crucial for the development of many important theories in mathematical analysis, which, in turn, has important implications on the study of random walk, a versatile model for many operations research applications, for detailed discussion on Burkholder's inequality and its applications, see, for example, Hall and Heyde [7].

Decoupling Inequalities

Understandably, independence among random variables provides convenience in probabilistic calculations. The purpose of decoupling inequalities is to use the functionals of the independent random variables to estimate the functionals of dependent random variables, such as martingales. Here

is a decoupling inequalities for martingales in a very general form.

Theorem 4 *Suppose that $X_n = \sum_{i=1}^n D_n$ and $(X_n, \mathcal{F}_n)$ is a martingale for some filtration $\mathcal{F}_n$. $\{E_i\}$ is an independent sequence of random variables such that, for each $i = 1, 2, \dots, E_i$ has the same probability law as that of D_i conditioning on $\mathcal{F}_{i-1}$. Then, for any convex function $\Phi(\cdot)$, there exist two constants c_α and C_α , such that*

$$\begin{aligned} c_\alpha \mathbb{E} \left[\Phi \left(\sup_n \left| \sum_{i=1}^n E_i \right| \right) \right] \\ \leq \mathbb{E} \left[\Phi \left(\sup_n \left| \sum_{i=1}^n D_i \right| \right) \right] \\ \leq C_\alpha \mathbb{E} \left[\Phi \left(\sup_n \left| \sum_{i=1}^n E_i \right| \right) \right], \end{aligned}$$

where $\|X\|$ denotes a general norm.

This type of decoupling inequalities are applied in the analysis of multi-item inventory systems to provide justification for reducing its analysis to that of the independent single-item inventory systems, see, for example, Ref. 8. A more comprehensive treatment of general decoupling inequalities and their application can be found in the book by de la Peña and Giné [9].

Concentration Inequalities

The concentration inequalities, closely related to the convergence theorems that are presented in the next section, describe quantitatively the phenomenon that a summation of random variables will not deviate from its expectation with a large probability. Here is a version that is accredited to Azuma and Hoeffding.

Theorem 5 (Azuma–Hoeffding). *Let $\{D_n\}$ be a martingale difference sequence, and $c_1, c_2, \dots, c_n$ are constants such that $|D_i| \leq c_i$ almost surely. Then for any $t > 0$, we have,*

$$\mathbb{P} \left[\max_{1 \leq k \leq n} \sum_{i=1}^k D_i > t \right] \leq \exp \left(-\frac{t^2}{2 \sum_{i=1}^k c_i} \right).$$

Concentration inequalities, essentially the Azuma's inequality, are instrumental in the analysis of random algorithms, see, for example, Ref. 10.

MARTINGALE LIMIT THEOREM

In this section, we first introduce Doob's martingale convergence theorems, then the law of large number and central limit theorems for martingale difference. A very important concept that is a key to some convergence theorems and optimal stopping is introduced and discussed in the next section.

Theorem 6 *If X_n is a submartingale, and there exist a $C > 0$, such that $E|X_n| \leq C$ for any $n \geq 1$, then there exists a random variable X , satisfies $E|X| < \infty$, such that $X_n \rightarrow X$ almost surely as $n \rightarrow \infty$.*

Definition 2 A family of random variables $X_n, n \geq 1$, is called *uniformly integrable* if

$$\lim_{x \rightarrow \infty} \int_{|X_n| > x} |X_n| dP = 0,$$

uniformly in $n \geq 1$.

In essence, the property of uniform integrability enables "truncation" operation, which is a very important technique in probability and analysis. In fact, we have,

Theorem 7 *The following three propositions are equivalent for a submartingale X_i :*

1. *It is uniformly integrable.*
2. *It converges in L^1 .*
3. *It converges almost surely to an integrable random variable X_∞ , with $E[X_n] \rightarrow E[X_\infty]$.*

A martingale can be treated as the summation of the martingale difference sequence; hence, it is natural to ask about its first- and second-order asymptotic behavior. In other words, do we have the law of large number and the central limit theorem?

The best result on the law of large number is obtained by Elton [11]. It indicates that, in comparison to the Marcinkiewicz–Zygmund theorem for independent and identically distributed random variables, where integrability of the random variables guarantees the almost sure convergence, a more restrictive integrability condition is required for establishing the law of large number for a martingale difference sequence. Define,

$$L \log L = \{X \in L^1 | E[|X| \log(|X| \vee 1)] < \infty\}.$$

We have,

Theorem 8 *If $D_n \in L \log L$, then $\frac{1}{n}X_n \rightarrow 0$ almost surely.*

In Elton's article, a counterexample is given for the case such that the law of large number fails to hold for a sequence that is only L^1 but not $L \log L$. The proof techniques displayed in Ref. 11 are also marvelous.

Meanwhile, requirements on second moment are needed for central limit theorem. The following version might not be in the most general form, but it provides a convenient tool for most of the problems encountered in the application.

Theorem 9 *Let S_{ni} be a zero-mean square integrable martingale for each n , and $X_{ni} = S_{ni} - S_{n,i-1}$, and η^2 is an almost surely finite random variable. Suppose that*

$$\max_i |X_{ni}| \rightarrow 0, \quad \text{in probability,}$$

$$\sum_i X_{ni}^2 \rightarrow \eta^2, \quad \text{in probability,}$$

$$E\left(\max_i X_{ni}^2\right) \text{ is bounded in } n,$$

then, $S_{nk_n} = \sum_i X_{ni} \rightarrow Z$ in distribution, where the random variable Z has the characteristic function $E \exp(-\frac{1}{2}\eta^2 t^2)$.

For more general results and deep discussions, please see Ref. 7, a wonderful resource of various limit theorems for martingales.

OPTIONAL STOPPING THEOREM

Recall that the expectation of the martingale equals to its initial value at any time. The optional stopping theorem (also known as *optional sampling theorem*) extends this property to allow the time to be random. More precisely, it allows the time to be a stopping time. This technique, as we can see from examples in this section, greatly enhances our ability to compute many probabilistic quantities.

Definition 3 A random variable τ taking value in nonnegative integers is called a stopping time (with respect to the filtration $\{\mathcal{F}_t\}$) if $\{\tau \leq n\} \in \mathcal{F}_n$ for any $n \geq 1$.

Intuitively, stopping time can be understood as a random time that depends on the history of the stochastic process. A concrete example, which may also partially explain the name, can be found in context of gambling or game, where the time to stop can depend on the outcome of the game or gambling. For example, a gambling stops when a player runs out of money, meanwhile, a tennis game stops when a player earns enough points.

An important stopping time widely studied in operations research and management science is the first passage time. For any stochastic process X_n , and a real number a , then T_a , the first passage time for X_n at level a is defined as,

$$T_a \triangleq \{n \geq 1 : X_n \geq a\}.$$

In other word, the first time that the process X_n takes a value above the level a .

One of the most important results on martingale is the following optional stopping theorem.

Theorem 10 For a martingale X_n and a stopping time τ , if the following conditions are satisfied,

- $P[\tau < \infty] = 1$,
- $E[|X_\tau|] < \infty$,
- $\lim_n \rightarrow \infty E[X_n \mathbf{1}\{\tau > n\}] = 0$.

Then, $E[X_\tau] = E[X_0]$.

There are also various optional stopping theorems, for details, see, for example, Ref. 12.

Example 6 One example will be the simple random walk, suppose that Y_i are independent and identically distributed random variables with $Y_i = 1$ or $Y_i = -1$ with probability $1/2$ respectively. Then $X_n = Y_1 + Y_2 + \dots + Y_n$ is a martingale, define, for any pair of positive integers a and b ,

$$T_{ab} = \min\{n \geq 1 : X_n = -a, \text{ or } X_n = b\}.$$

Define p_a the probability of X_n reach a first, then, optimal stopping yields,

$$E[X_{T_{ab}}] = (-a)p_a + b(1 - p_a) = 0.$$

Hence, $p_a = \frac{b}{a+b}$. Next, define $Z_n = X_n^2 - n$. It is easy to see that Z_n is a martingale, too. Apply optional stopping to Z_n , we can get that $E[T_{ab}] = ab$.

Example 7 (Walds' identities). X_i are independent and identically distributed random variables, with $E[X_1] = \mu < \infty$, $E[X_1^2] < \infty$, and T is a stopping time, then we have,

$$E[S_T] = \mu E[T], E[S_T^2] = E[T]E[X_1^2].$$

MARTINGALE WITH CONTINUOUS PARAMETERS AND BROWNIAN MOTION

The concept of martingale can be extended naturally to continuous-time processes.

Definition 4 A continuous-time stochastic process X_t is a martingale with respect to the filtration $\{\mathcal{F}_t\}$, if it satisfies,

1. $X_t \in \mathcal{F}_t$,
2. $E[|X_t|] < \infty$,
3. $E[X_t | \mathcal{F}_s] = X_s$, for any $s \leq t$.

Inequalities and convergence theorems can be adapted to the continuous version in a straightforward manner.

One of the most important **Continuous-Time Martingales** is Brownian motion. Here, we reflect on some basic properties of the Brownian motion, as well as some important applications of the optional stopping rule.

Definition 5 Brownian motion, $B(t)$, is defined as a Gaussian process with mean zero, and correlation $E[B_s B_t] = \min(s, t)$ for any s and t .

Almost surely, the sample path of Brownian motion is continuous, but nowhere differentiable. It is also an important example of diffusion processes, that is, Markov processes with continuous sample path almost surely. Diffusion processes play a vital role in the development of financial mathematics and stochastic control.

At any time $t \geq 0$, $B(t)$ follows normal distribution with mean zero and variance t , hence with density function,

$$\phi_t(x) = \frac{1}{\sqrt{2\pi t}} e^{-\frac{x^2}{2t}}, \quad x \in \mathbb{R}.$$

One of the most important results for Brownian motion is the distribution of the running maximum of the Brownian motion. Denote $M(t) = \max_{0 \leq s \leq t} B(s)$, we have,

$$\begin{aligned} P[B(t) \in dx, M(t) \in dy] &= \frac{2(2y-x)}{\sqrt{2\pi t^3}} \exp\left\{-\frac{(2y-x)^2}{2t}\right\} dx dy, \\ P[M(t) \in dx] &= \frac{2}{\sqrt{2\pi t}} \exp\left(-\frac{x^2}{2t}\right) dx. \end{aligned}$$

HISTORICAL NOTES AND FURTHER READINGS

The term *martingale* was first introduced to mathematics by Jean Ville [13] in 1939. However, mathematicians Sergey Berntein and Paul Levy had investigated dependent

random variables that have martingale structures before that. There are various explanations for the origin of word “martingale” and its meanings in the game of gambling, a good resource for these stories is a recent article by Roger Mansuy [14].

Joseph Leo Doob [15] derived some fundamental results on martingales in the 1940s and 1950s. Many of these results are presented elegantly in his 1953 classic *Stochastic Processes*, and a more comprehensive treatment of martingales is presented in his later less popular book *Classical Potential Theory and Its Probabilistic Counterpart* [22]. Doob is considered by many as the “founding father of the theory of martingales” [14].

Donald Burkholder developed some fundamental results on martingales in the 1960s and 1970s. Especially, his work on martingale inequalities has deep impact in the development of harmonic analysis, some of his ideas are still actively explored by researchers today. His work on martingale transform laid foundation for the development of stochastic calculus.

The mature and fast growing of financial mathematics has brought a large new influx of ideas and problems to martingale theory and application. The key object in the development of this area is Brownian motion, a martingale with continuous parameter. While observed and studied by physicists from the nineteenth century, the first mathematical construction of Brownian motion was only obtained by Norbert Wiener [16] in 1923. During the 1940s and 1950s, Kiyoshi Ito developed the stochastic calculus method to study general Markov processes. It becomes the basis of financial mathematics.

There are some excellent textbooks available for martingales. For readers with strong mathematical background, Chapter 9 in Kai-Lai Chung’s [17] classic textbook is always considered as a wonderful introduction to the topic. Less technical savvy books, such as [12] and [18] are good ones for general audiences. The book by Chow and Teicher [19] provides deep discussions on many aspects of martingale theory. Hall and Heyde [7] discusses in details on various limit theorems. Karatzas and Shreve [20] and Reeuz and Yor

[21] are two good sources for fundamentals on continuous-time martingale.

Certainly, there are so many very interesting and important topics that we are not able to cover. These include, but not limited to, martingale problem in Markov processes, martingale's role in functional central limit theorems, martingales in Levy processes, and martingale transform.

TOTAL EXPECTED DISCOUNTED REWARD MDPs: EXISTENCE OF OPTIMAL POLICIES

EUGENE A. FEINBERG
Department of Applied
Mathematics and Statistics,
State University of New
York at Stony Brook, Stony
Brook, New York

INTRODUCTION

Deterministic optimal policies always exist for discounted dynamic programming problems with finite action sets. Such policies also exist when action sets satisfy certain compactness conditions, and transition probabilities and reward functions satisfy certain continuity conditions. If either compactness or continuity conditions do not hold, deterministic ϵ -optimal policies exist for problems with countable state spaces. For problems with uncountable Borel-state spaces, the results similar to the existence of deterministic ϵ -optimal policies hold but in this more general case, either the notion of ϵ -optimality should be replaced with the weaker notion of (p, ϵ) -optimality or a broader definition of a policy is required. Since the theory is simpler when the state space is countable, problems with countable and uncountable state spaces are considered separately in this article.

COUNTABLE STATE SPACE

Definitions

Consider a Markov decision process (MDP) with the state space X , action space A , sets of actions $A(x)$ available at states $x \in X$, transition probabilities p , and rewards r . We assume throughout this section that the state space X is countable. In particular, it can be either finite or countably infinite.

We assume that the action set A is a complete, separable metric space. For simplicity, A can be imagined as a finite set, countably infinite set, R^n , or its natural subset. All sets $A(x)$ are nonempty Borel subsets of A . In particular, if A is countable then $A(x)$ are arbitrary nonempty subsets of A .

If an action $a \in A(x)$ is selected at the state x , then the one-step reward is $r(x, a)$ and the probability that the system will be at the state y at the next step is $p(y|x, a)$. The standard assumption is that the functions $r(x, a)$ and $p(y|x, a)$ are measurable in a for all $x, y \in X$.

Unless specified, we shall assume that the sum of transition probabilities is 1 and the reward function is bounded above. The former means that $\sum_{y \in X} p(y|x, a) = 1$ for all $x \in X$ and for all $a \in A(x)$. The latter means that there exists a finite constant K such that $r(x, a) \leq K$ for all $x \in X$ and for all $a \in A(x)$.

For the classical dynamic programming problems introduced by Blackwell [1], the reward functions $r(x, a)$ are assumed to be bounded, that is, $|r(x, a)| \leq K$, $x \in X$ and $a \in A(x)$, for some finite constant K . However in many operations research applications, the reward functions are bounded above, that is, $r(x, a) \leq K$ when $x \in X$ and $a \in A(x)$. For example, in mathematical models of inventory and queueing systems, the one-step holding costs can tend to ∞ as the inventory levels or number of waiting customers increases to ∞ . Therefore, the corresponding reward functions can be unlimited from below. So, we consider the more general case when the reward function is bounded from above.

A general policy may be randomized and history-dependent. Let Π be the set of all policies. A deterministic policy is defined as a function ϕ that always selects action $\phi(x)$ at a state $x \in X$. In other words, a deterministic policy is history-independent and nonrandomized. Let $\mathcal{D}$ denote the set of deterministic policies.

Let the initial state be x and a policy π be chosen. For a positive constant $\alpha < 1$ called a *discount factor*, the expected total discounted

reward is

$$v^\pi(x) = E_x^\pi \sum_{n=0}^{\infty} \alpha^n r(x_n, a_n),$$

where E_x^π is the expectation when the initial state is x and a policy π is chosen, and x_t and a_t are states and selected actions at epochs $t = 0, 1, \dots$. The value at each state x is defined as $V(x) = \sup_{\pi \in \Pi} v^\pi(x)$.

A policy π is called optimal if $v^\pi(x) = V(x)$ for all $x \in X$. Thus, the optimality is defined with respect to all possible initial states. If an optimal policy is deterministic, it is called a *deterministic optimal policy*.

A policy π is called ϵ -optimal for a nonnegative constant ϵ if $v^\pi(x) \geq V(x) - \epsilon$ for all initial states x from X . In particular, the notions of 0-optimal and optimal policies coincide.

For $x \in X$, $a \in A(x)$, and for a bounded above real-valued function f on X , define

$$T^a f(x) = r(x, a) + \alpha \sum_{y \in X} p(y|x, a) f(y).$$

This value can be interpreted as the expected reward over two steps starting from the state x , when the action a from $A(x)$ is selected and the reward at the second step is defined by the function f . For a deterministic policy ϕ , we can consider the operator T^ϕ defined for functions f bounded above,

$$T^\phi f(x) = T^{\phi(x)} f(x), \quad x \in X.$$

Then

$$v^\phi(x) = T^\phi v^\phi(x), \quad x \in X. \quad (1)$$

The optimality operator T is defined as

$$Tf(x) = \sup_{a \in A(x)} T^a f(x), \quad x \in X.$$

The value function V satisfies the *optimality equation*

$$U(x) = TU(x), \quad x \in X. \quad (2)$$

In particular, if the reward function r is bounded, then T^ϕ and T are contraction mappings defined on the set of bounded functions

on X endowed with the metric d induced by supremum norms. This is true for an arbitrary, possibly uncountable, set X . The supremum norm $\|v\|$ of a bounded function v on X is $\|v\| = \sup_{x \in X} |v(x)|$. The metric d is defined as $d(v, u) = \|u - v\| = \sup_{x \in X} |v(x) - u(x)|$. The contraction mapping property in our case means that $d(T^\phi v, T^\phi u) \leq \alpha d(v, u)$ and $d(Tv, Tu) \leq \alpha d(v, u)$.

Therefore, when the reward function r is bounded, the Banach fixed point theorem (also known as the *contraction mapping theorem* or *contraction mapping principle*) implies that the functions v^ϕ and V are the unique bounded solutions of the equations $u = T^\phi u$ and $U = TU$, respectively. The Banach fixed point theorem also provides the convergence of the value iteration algorithm and it provides estimates for its convergence; see Bertsekas [2, Chapter 1] on such estimates and Feinberg [3] on convergence of value iterations for total-reward criteria. We notice that in addition to a unique bounded solution, each of these equations may have unbounded solutions (Example 6.4 in Ref. 3).

The analysis of discounted problems with reward functions bounded above can be reduced to the analysis of a negative dynamic programming problem by replacing the reward function r with the nonpositive reward function $\tilde{r} = r - K$. Then the expected total-reward $\tilde{v}^\pi$ for the new problem is $\tilde{v}^\pi(x) = v^\pi(x) - K/(1 - \alpha)$ for all $x \in X$ and for all $\pi \in \Pi$. Therefore, the existence of optimal and ϵ -optimal policies for discounted problems can be obtained from the corresponding results for negative programming. For example, for negative programming, the value function is the largest solution of Equation (2) with $\alpha \in [0, 1]$. Therefore, if the reward function r is bounded above for a discounted dynamic programming problem, then the value function V is the largest solution of Equation (2) satisfying the inequality $U(x) \leq K/(1 - \alpha)$ for all $x \in X$. However, stronger results sometimes hold for discounted problems rather than for negative problems. The optimality equation and its properties are summarized in the following theorem.

Theorem 1. *The value function V is the largest solution of the optimality equation (Eq. 2), satisfying the inequality $U(x) \leq K/(1 - \alpha)$ for all $x \in X$. If the reward function r is bounded, then V is the unique bounded solution of the optimality equation (Eq. 2).*

In a similar way, discounted MDPs with reward functions bounded below can be reduced to positive dynamic programming. Such reward functions are used in some economics applications.

Existence of Optimal Policies

A deterministic policy ϕ is called *conserving* if $T^\phi V(x) = V(x)$ for all $x \in X$.

Theorem 2. *A deterministic policy ϕ is optimal if and only if it is conserving.*

Therefore, the existence of a deterministic optimal policy and the existence of a conserving policy are equivalent statements. Finding a deterministic optimal policy is equivalent to finding a conserving policy. Consider the sets of conserving actions

$$A_c(x) = \{a \in A(x) \mid T^a V(x) = V(x)\}, \quad x \in X.$$

Theorem 2 implies that a deterministic optimal policy exists, if and only if $A_c(x) \neq \emptyset$. In addition, the optimality equation implies that $v^\pi(x) < V(x)$ for any policy π if $A_c(x) = \emptyset$. Therefore, Theorem 2 implies the following corollary.

Corollary 1. *An optimal policy exists if and only if for each $x \in X$ the set of conserving actions $A_c(x)$ is not empty. In addition if an optimal policy exists, then there exists a deterministic optimal policy.*

Thus, it is sufficient to verify $A_c(x) \neq \emptyset$ for all $x \in X$ to prove the existence of optimal deterministic policies. In particular, since $V = TV$, optimal policies exist if all the sets $A(x)$ are finite. However, they also exist under more general assumptions.

Definition 1. A real-valued function f defined on a topological space Z is called

sup-compact if the set $Z^\lambda = \{z \in Z \mid f(z) \geq \lambda\}$ is compact for any real number λ .

The following assumption is sufficient for $A_c(x) \neq \emptyset$ for all $x \in X$.

Assumption 1.

- (i) For each $x, y \in X$, the function $p(y \mid x, a)$ is continuous in $a \in A(x)$.
- (ii) For each $x \in X$, the function $r(x, a)$ is sup-compact in $a \in A(x)$. This means that for any $x \in X$ and for any number λ , the set $A^\lambda(x) = \{a \in A(x) \mid r(x, a) \geq \lambda\}$ is compact.

Assumption 1 implies that all the sets of conserving actions $A_c(x)$ are nonempty and therefore the following statement holds.

Corollary 2. *If an MDP satisfies Assumption 1, then there exists a deterministic optimal policy.*

The following assumption is stronger than Assumption 1.

Assumption 2.

- (i) Assumption 1(i) holds.
- (ii) The set $A(x)$ is compact for each $x \in X$.
- (iii) For each $x \in X$ the reward function $r(x, a)$ is upper semi-continuous in $a \in A(x)$.

Corollary 3. *If an MDP satisfies Assumption 2, then there exists a deterministic optimal policy.*

In particular, Assumption 2 holds when all the sets $A(x)$ are finite. Therefore, the above mentioned fact on the existence of optimal policies for finite action sets can be formulated as a particular case of Corollary 3.

Corollary 4. *If for each state $x \in X$ the set of available actions $A(x)$ is finite, then there exists a deterministic optimal policy.*

According to the above statements, the existence of optimal policies requires certain continuity and compactness conditions to ensure the existence of conserving actions for all states. The existence of deterministic ϵ -optimal policies, where ϵ is an arbitrary fixed positive number, does not require such conditions.

Let ϵ be a positive constant. Consider a deterministic policy ϕ such that $T^\phi(x)V(x) \geq TV(x) - (1 - \alpha)\epsilon$ for all $x \in X$. Then the optimality equation $V = TV$ and straightforward calculations imply that $v^\pi(x) \geq V(x) - \epsilon$ for all $x \in X$. Therefore, the following result holds.

Theorem 3. *For any $\epsilon > 0$ there exists a deterministic ϵ -optimal policy.*

BOREL-STATE PROBLEMS

A topological space $(E, \mathcal{T})$ is called *Polish* if it is separable and completely metrizable. We recall that a topological space E is called *completely metrizable*, if it admits a compatible metric d such that (X, d) is a complete metric space. A Borel σ -field on a topological space $(E, \mathcal{T})$ is defined as the minimal σ -field on E containing all the open subsets from E . A subset of B is called *Borel* if it belongs to the Borel σ -field on B .

A measurable space $(B, \mathcal{B})$ is called *Borel* (or *standard Borel*), if there is a one-to-one measurable mapping $f : B \rightarrow [0, 1]$ such that $f(B)$ is a Borel subset of the interval $[0, 1]$. Any Polish space B is a Borel space with $\mathcal{B}$ being the Borel σ -field on B . In addition, any Borel space and, therefore, any Polish space is either countable or continuum (Appendix 1 of Ref. 4 or Corollary 7.16.1 of Ref. 5). Countable sets include finite sets. If a Borel space B is continuum, there is a measurable one-to-one mapping of B on the interval $[0, 1]$. If two Borel spaces B_1 and B_2 have the same cardinality, there is a measurable one-to-one mapping of B_1 on B_2 such that the mapping f^{-1} is measurable too.

Any countable or continuum set is Polish in the appropriate topology. If a set is countable, it is Polish if the discrete topology on it is chosen. If a set B is continuum, we can choose any one-to-one correspondence

$f : B \rightarrow [0, 1]$ of B on the interval $[0, 1]$, and define the topology on B , whose basis consists of the proimages $f^{-1}(C)$ of all open intervals $C = (y, z) \subset [0, 1]$. In particular, if B is a Borel space, then f can be selected as measurable. Therefore, any Borel space is a Polish space in the described topology.

Let $(B, \mathcal{B})$ be a Borel space and $\mathcal{P}(B)$ be the set of all probability measures on $(B, \mathcal{B})$. For any probability measure p on $(B, \mathcal{B})$, consider the p -completion $\mathcal{B}_p$ of $\mathcal{B}$, that is, $\mathcal{B}_p$ is the minimal σ -field containing $\mathcal{B}$ and any subset Y of B such that $Y \subset C$ for some $C \in \mathcal{B}$ with $p(C) = 0$. The σ -field $\mathcal{U} = \bigcap_{p \in \mathcal{P}(B)} \mathcal{B}_p$ is called the *universal σ -field*. A subset C of B is called *universally measurable* if $C \in \mathcal{U}$. A function $f : B \rightarrow Y$, where B and Y are Borel spaces, is said to be *universally measurable*, if $f^{-1}(C)$ is universally measurable for any Borel set $C \subseteq Y$. If f is a universally measurable function and p is a probability measure on $(B, \mathcal{B})$, then there exists a Borel function f_p such that $P(\{z : f(z) \neq f_p(z)\}) = 0$. Thus, universally measurable functions $f : B \rightarrow R$ can be integrated with respect any probability measure on $(B, \mathcal{B})$ in the same way as Borel-measurable functions.

A Borel-state MDP is defined by the same objects as the MDP with a countable state space. The differences are that (i) the state space X is a Borel space, (ii) the transition probability $p(E|x, a)$ is a probability measure on the Borel σ -field of X and it satisfies the condition that for any Borel subset Y of X the function $p(Y|x, a)$ is measurable in $(x, a) \in X \times A$.

A general policy is defined by transition probabilities π_n , $n = 0, 1, \dots$ such that for any $h_n = x_0, a_0, x_1, a_1, \dots, a_n$, $\pi_n(da_n|h_n)$ is a probability measure on A satisfying the following two conditions: (i) $\pi_n(A(x_n)|h_n) = 1$ and (ii) for each Borel subset B of A , the function $\pi_n(B|h_n)$ is Borel-measurable on the set of all histories H_n up to time n , $H_n = X \times (A \times X)^n$. Thus, a general policy can be randomized and history-dependent.

The following assumption is standard for Borel-state MDPs and is always assumed in this article: the graph

$$\text{Gr}(A) = \{(x, a) | x \in X, a \in A(x)\}$$

is a Borel subset of $X \times A$. A deterministic policy is a measurable mapping of X to A such that $\phi(x) \in A(x)$ for all $x \in X$. In other words, $(x, \phi(x)) \in \text{Gr}(A)$ for all $x \in X$. In general, for some $D \subset X \times A$, a mapping $f: X \rightarrow A$ is called a *selector* if $(x, f(x)) \in D$ for all $x \in X$. So, a deterministic policy is a measurable selector from X to A with respect to $D = \text{Gr}(A)$. So, a deterministic policy is sometimes called a *measurable selector*.

In order to define at least one policy and avoid the possibility that $\Pi = \emptyset$, we need to assume that there exists at least one deterministic policy. We shall avoid this assumption by using the convention that $\sup\{\emptyset\} = -\infty$. Then, $V(x) = -\infty$ for all $x \in X$, if $\Pi = \emptyset$. In many cases, for example, under Assumptions S, Su, W, and Wu and for universally measurable policies described below, $\Pi \neq \emptyset$, because the existence of a deterministic policy follows from so-called *measurable selection theorems*.

A special feature of the above model is that the value function V may not be Borel-measurable. However, it belongs to a broader class of universally measurable functions, for which integration is possible. In the same way, we had for the countable state set, the value function V satisfies the optimality equation. In the case of a bounded reward function r , the value function is a unique bounded universally measurable function. This is true if either the existence of at least one deterministic policy is assumed or policies are allowed to be selected from a broader class of universally measurable policies.

For Borel-state models, the statements similar to Theorems 1 and 2 hold.

Theorem 4.

- (i) *The value function V is universally measurable and it is a solution of the optimality equation (Eq. 2).*
- (ii) *The value function V is the largest universally measurable solution U of the optimal equation (Eq. 2), such that $U(x) \leq K/(1 - \alpha)$ for all $x \in X$.*
- (iii) *If the reward function r is bounded, then V is the unique bounded solution of the optimality equation (Eq. 2).*

Theorem 5. *A deterministic policy is optimal if and only if it is conserving.*

In addition, the following statement holds.

Theorem 6. *If there exists an optimal policy, then there exists a deterministic optimal policy.*

To ensure the existence of conserving policies, some continuity and compactness properties are required. Before we describe particular cases, we formulate a general statement.

For a policy π , let v_N^π denote the N -horizon expected discounted total rewards. We have $v_0^\pi(x) = 0$, $x \in X$, and for $N = 1, 2, \dots$

$$v_N^\pi(x) = E_x^\pi \sum_{n=0}^{N-1} \alpha^n r(x_n, a_n), \quad x \in X.$$

Let $V_N(x) = \sup_{\pi \in \Pi} v_N^\pi(x)$. According to these definitions, $V_0(x) = 0$ for all $x \in X$. In the trivial case, when $\Pi = \emptyset$ we have $V_N(x) = -\infty$, for all $x \in X$ and for all $N = 1, 2, \dots$. The values $V_N(x)$ is the supremum of the expected total-reward over the finite-horizon N with the 0 terminal value V_0 . As was shown by Blackwell [1], the functions V_N , $N = 1, 2, \dots$ and N belong to the class of universally measurable functions and therefore they can be integrated in the same way as Borel functions. In addition, the function V_N satisfies the optimality equation $V_{N+1} = TV_N$, $N = 0, 1, \dots$. This is the well-known optimality equation for finite-horizon dynamic programming models. It can be proved by inductions or as a corollary from Theorem 4(i), because a finite-horizon model can be reduced to an infinite-horizon model [3, Section 4.6]. The following theorem provides a sufficient condition for the existence of optimal deterministic policies.

Theorem 7. *Suppose that there exists a nonnegative integer k such that for any $x \in X$, for any finite number λ , and for any $N \geq k$ the set*

$$A_N^\lambda(x) = \left\{ a \in A(x) \mid r(x, a) + \alpha \int V_N(y) p(dy \mid x, a) \geq \lambda \right\}$$

is a compact subset of A . Then $V(x) = \lim_{N \rightarrow \infty} V_N(x)$ for all $x \in X$, and there exists a deterministic optimal policy.

Theorem 7 is a useful tool to establish the existence of deterministic optimal policies under an assumption similar to Assumption 5. When X is continuum, there are two groups of assumptions in the literature corresponding to Assumption 5. These assumptions correspond to two different types of convergence of probability measures: setwise convergence and weak convergence. Such assumptions, the so-called S and W were introduced by Schäl [6,7] for the case of compact action spaces. Since we start with possibly noncompact action sets, we shall use abbreviations Su and Wu, where the symbol “u” indicate that the sets $A(x)$ can be unbounded and therefore noncompact. In many applications, noncompact action sets are unbounded.

Assumption Su (i) For each $x \in X$, the transition probability $p(dy|x, a)$ is setwise continuous in $a \in A(x)$. This means that $p(Y|x, a_n) \rightarrow p(Y|x, a)$ for every $x \in X$ and for any sequence $a_n, n = 1, 2, \dots$, of elements of $A(x)$ converging to a , where Y is an arbitrary measurable subset of X .

(ii) For each $x \in X$, the reward function $r(x, a)$ is sup-compact in a , that is, the set $A^\lambda(x) = \{a \in A(x) | r(x, a) \geq \lambda\}$ is compact for any real number λ .

Assumption Wu.

- (i) The transition probability $p(dy|x, a)$ is weakly continuous in $(x, a) \in X \times A$, that is, for any bounded continuous function f on X

$$\int f(y) p(dy|x_i, a_i) \rightarrow \int f(y) p(dy|x, a),$$

for any $x \in X$ and any $a \in A(x)$, if $(x_i, a_i) \rightarrow (x, a)$ and $a_i \in A(x_i)$.

- (ii) The reward function $r(x, a)$ is sup-compact on $\text{Gr}(A)$, that is, the set $\{(x, a) \in \text{Gr}(A) | r(x, a) \geq \lambda\}$ is compact for any finite number λ .

Theorem 8. *Either Assumption Su or Assumption Wu implies the existence of a deterministic optimal policy. In addition, the value function V is Borel measurable under Assumption Su and sup-compact under Assumption Wu.*

The following assumptions are sufficient for the existence of deterministic optimal policies when all the sets of available actions $A(x)$ are compact.

Assumption S.

- (i) The sets $A(x)$ are compact for all $x \in X$.
- (ii) The transition probability $p(\cdot|x, a)$ is setwise continuous in $a \in A(x)$, that is, Assumption Su(i) holds.
- (iii) The reward function $r(x, a)$ is upper semi-continuous in $a \in A(x)$ for all $x \in X$.

Assumption W.

- (i) The sets $A(x)$ are compact for all $x \in X$.
- (ii) The set-valued mapping $A(x)$ is upper semicontinuous; that is, for any open subset G of A , the set $\{x \in X | A(x) \subseteq G\}$ is open in X .
- (iii) The transition probability $p(\cdot|x, a)$ is weakly continuous on $(X \times A)$, that is, Assumption Wu(i) holds.
- (iv) The reward function $r(x, a)$ is upper semicontinuous on $\text{Gr}(A)$.

Theorem 9. *Under each Assumption S or W, there exists a deterministic optimal policy. In addition, the value function V is Borel-measurable under Assumption S and upper semicontinuous under Assumption W.*

The following corollary follows from Theorem 9 under Assumption S.

Corollary 5. *If each set $A(x), x \in X$, is finite, then there exists a deterministic optimal policy.*

Now we discuss the existence of ϵ -optimal policies. For expected discounted reward

MDPs with countable state spaces, deterministic ϵ -optimal policies always exist (Theorem 3). For a Borel-state space, this is true if all the sets of available actions $A(x)$ are countable. In this case, there always exists a deterministic policy, $V(x)$ is a Borel-measurable function, and the following theorem holds.

Theorem 10. *If all the action sets $A(x)$, $x \in X$ are countable, then for any $\epsilon > 0$ there exists a deterministic ϵ -optimal policy.*

In a general situation, the value function $V(x)$ may not be Borel measurable, but it is universally measurable, see Refs 1, 4, and 5 for detail. Since for any fixed policy π the function $v^\pi(x)$ is Borel, ϵ -optimal policies may not exist [1, Example 2]. However, such policies exist if either the definition of ϵ -optimal is changed to the definition of so-called (p, ϵ) -optimal policies or the set of policies is expanded by allowing the policies to be universally measurable.

Let p be a probability measure on X . A policy π is called (p, ϵ) -optimal if there exists a measurable subset Y of X such that $p(Y) = 1$ and $v^\pi(x) \geq V(x)$ for all $x \in Y$.

Theorem 11. *For any probability measure p on X and for any $\epsilon > 0$, there exists a deterministic (p, ϵ) -optimal policy.*

However, for any $\epsilon > 0$ there exists a deterministic ϵ -optimal policy, if the definition of a policy is expanded by allowing transition probabilities $\pi_n(B|h_n)$ to be universally measurable functions on X for all Borel-measurable subsets B of A . A deterministic universally measurable policy ϕ is a universally measurable mapping from X to A such that $\phi(x) \in A(x)$ for all $x \in X$. The Jankov–von Neumann selection theorem implies that there exists at least one universally measurable deterministic policy, details in Bertsekas and Shreve [5], Dynkin and Yushkevich [4], and Kechris [8]. We also remark that the value function V remains unchanged after the set of Π is extended by allowing universally measurable policies, except the trivial case when there is no Borel-measurable selector from X to A .

Theorem 12. *If universally measurable policies are allowed then for any $\epsilon > 0$ there exists a deterministic universally measurable ϵ -optimal policy.*

BIBLIOGRAPHIC NOTES

The literature on discounted MDPs is vast and we mention only a few references. Shapley [9] studied stochastic games with discounted payoffs. Dubins and Savage [10] and then Hordijk [11] studied the relations between conserving and optimal policies. In particular, a deterministic policy for an MDP with the expected total criterion is optimal, if and only if it is conserving and equalizing. However, any policy is equalizing for a discounted MDP with a reward function $r(x, a)$ bounded above. So, Theorem 2 can be traced to Dubins and Savage [10]. Theorem 5 is a straightforward extension of Theorem 2 to problems with Borel-state spaces.

Blackwell [1] studied a discounted Borel-state MDP with bounded rewards. Theorems 6, 10, and 11 are from Ref. 1. Strauch [12] proved the universal optimality of the value function and optimality equation (Theorem 4). Blackwell [1] and Strauch [12] considered a model when $A(x) = A$ for all $x \in X$. Dynkin and Yushkevich [10] extended the theory in several directions including the state-dependent action sets $A(x)$. Denardo [13] studied contraction properties of dynamic programming operators. In particular, these properties lead to Theorem 3. This theorem can be viewed as a particular case of Theorem 6.21 from Feinberg [3], which describes the structure of nearly optimal policies in countable MDPs with expected total rewards [14].

Theorem 7 is Proposition 9.17 from Bertsekas and Shreve [5]. Schäl [6,7] introduced Assumptions S and W, where S stands for setwise continuity of transition probabilities and W stands for weak continuity. Theorem 9 is from Schäl [7]. The monograph by Hernández-Lerma and Lasserre [15] primarily covers MDPs with setwise continuous transition probabilities. Assumption Su is from Hernández-Lerma [16] and Assumption Wu is from Feinberg and Lewis [17].

Theorem 8 presents the results from Refs 16 and 17. The answer to the question on which type of continuity is more appropriate depends on a particular application. For example, in Ref. 17, it was observed that Assumption Wu is applicable to inventory control problems with continuous demand distributions, while Assumption Su is applicable to inventory control problems with general demand distributions.

Blackwell *et al.* [18] and Freedman [19] investigated discounted MDPs with analytically measurable policies. Bertsekas and Shreve [5] developed the theory of dynamic programming on Borel-state spaces and universally measurable policies. Theorem 12 is from Ref. 5.

The theory of Borel spaces and measurable selection theorems play an important role in studying dynamic programming problems with Borel-state spaces. In addition to excellent chapters and appendices in Bertsekas and Shreve [5], Dynkin and Yushkevich [4], and Hernández-Lerma and Lasserre [15], the monograph by Kechris [8] contains important facts on these topics.

TOTAL EXPECTED DISCOUNTED REWARD MDPs: POLICY ITERATION ALGORITHM

Z. GOZDE ICTEN
SERDAR KARADEMIR
LISA M. MAILLART
Department of Industrial
Engineering, University of
Pittsburgh, Pittsburgh,
Pennsylvania

Policy iteration (PI), or search in policy space, was originally developed by Bellman [1] and independently by Howard [2] to solve Markov decision processes (MDPs). For an introduction to MDPs, please see the articles titled **MDP Basic Components** and **Total Expected Discounted Reward MDPs: Existence of Optimal Policies** in this encyclopedia. In this article, we restrict our attention to stationary infinite horizon MDPs under the total expected discounted reward criterion.

The PI algorithm requires one of the following sets of conditions [3]:

1. finite-state and action sets, and we assume that this assumption holds throughout the article;
2. finite-state space, compact action sets, and continuous reward and transition probabilities;
3. countable state space, compact action sets, and bounded continuous reward and transition functions.

The main idea of PI is to begin with an initial arbitrary policy and iteratively obtain improved policies until an optimal one is found, which is guaranteed to occur in a finite number of iterations under a specific set of conditions. The rest of the article is

organized as follows. We first give details of the PI algorithm and discuss its convergence properties. After demonstrating PI on a numerical example, we present the modified policy iteration (MPI) algorithm. Finally we illustrate MPI algorithm with an example and conclude the article.

POLICY ITERATION ALGORITHM

Define S as the state space of the process, A as the set of all possible actions, and D as the set of policies on $S \times A$. Let R be the set of bounded rewards defined on $S \times A$, and V be the space of bounded value vectors. Then, $A_s \subseteq A$ is the set of possible actions in state $s \in S$ and $r(s, a) \in R$ is the immediate expected reward received if action $a \in A$ is taken in state $s \in S$. The transition probability matrix defined under action $a \in A$ is denoted as $P(a)$ and the entry $p(s'|s, a)$ of $P(a)$ represents the transition probability to state $s' \in S$ from state $s \in S$ if action $a \in A_s$ is taken. Furthermore, we define λ to be the one-period discount factor, $0 < \lambda < 1$.

Let $v(s)$ be the total expected discounted reward starting in state $s \in S$ and following the optimal policy thereafter. The Bellman optimality equations are given by

$$v(s) = \max_{a \in A_s} \left\{ r(s, a) + \lambda \sum_{j \in S} p(j|s, a) v(j) \right\}, \quad \forall s \in S. \quad (1)$$

In vector notation, Equation (1) can be written as

$$v = \max_{d \in D} \{ r_d + \lambda P_d v \}, \quad (2)$$

where P_d is the transition probability matrix under policy d . We now give the details of PI algorithm.

Policy Iteration Algorithm [3]

1. Set $n = 0$ and select an arbitrary policy $d_0 \in D$.
2. (Policy Evaluation) Obtain v^n by solving the system of equations given by

$$(I - \lambda P_{d_n}) v^n = r_{d_n}, \quad (3)$$

where I denotes identity matrix of dimension $|S| \times |S|$.

3. (Policy Improvement) Choose d_{n+1} to satisfy

$$d_{n+1} \in \operatorname{argmax}_{d \in D} \{r_d + \lambda P_d v^n\} \quad (4)$$

setting $d_{n+1} := d_n$ if possible.

4. If $d_{n+1} = d_n$, return $d^* := d_n$. Otherwise set $n := n + 1$ and go back to step 2.

Each pass through the PI algorithm starts by calculating the “value vector,” v^n , for the current policy, d_n (Step 2). Remember that a policy is a mapping that assigns a single action to each state in the state space. Each element of the value vector is the corresponding total expected discounted reward for an initial state the process occupies under policy d_n . Under finite state and action sets, obtaining the value vector corresponds to solving a linear system of equations of size $|S|$. This step usually requires implementation of Gaussian elimination to solve the system. However, note that as the cardinality of the decision space, $S \times A$, increases, the computational burden of this step gets prohibitive, which is the main drawback of the policy iteration algorithm. MPI addresses this shortcoming.

After evaluating the current policy, the algorithm tries to improve the current policy (Step 3). If an improvement is found, the algorithm performs another iteration. Otherwise the algorithm stops and reports the current policy as the optimal one.

CONVERGENCE OF THE PI ALGORITHM

The policy iteration algorithm yields a sequence of policies and value functions. For processes with finite-state and action sets, this sequence is finite and the algorithm terminates in a finite number of iterations.

Finite convergence occurs with certainty, since the set of all possible policies is finite and therefore an improving policy is generated at each iteration. This convergence property of the policy iteration algorithm is its main advantage over the value iteration algorithm, which, in general, converges in an infinite number of iterations.

On the other hand, for a process with a compact action set and/or a countable state space, for which the number of policies is infinite, the stopping criterion in Step 4 may never be satisfied. In this case, a different approach must be used to demonstrate convergence of the algorithm. For further details, please refer to Puterman [3], Puterman and Brumelle [4], Puterman and Hordijk [5], and Golubin [6].

The following proposition from Puterman [3] establishes the convergence of the PI algorithm.

Proposition 1. *Let v^n and v^{n+1} be two successive value vectors generated by the PI algorithm and the operator $\succeq$ stand for componentwise comparison of two vectors. Then,*

$$v^{n+1} \succeq v^n.$$

Proof. If d_{n+1} satisfies Equation (4), then, by Equation (3)

$$r_{d_{n+1}} + \lambda P_{d_{n+1}} v^n \succeq r_{d_n} + \lambda P_{d_n} v^n = v^n.$$

Rearranging the terms yields

$$r_{d_{n+1}} \succeq (I - \lambda P_{d_{n+1}})v^n.$$

Hence,

$$\begin{aligned} (I - \lambda P_{d_{n+1}})^{-1} r_{d_{n+1}} &\succeq v^n \\ v^{n+1} &\succeq v^n, \end{aligned} \quad (5)$$

where inequality (5) follows from Lemma 6.1.2(b) in Puterman [3].

Proposition 1 establishes the monotonicity of the sequence $\{v^n\}$ which is key to the convergence of the PI algorithm.

Step 1. Set $n = 0$ and select the initial policy as $d_0(1) = 0$ and $d_0(2) = 1$.

Step 2. Solving of the following linear system of equations

$$\begin{aligned} v^0(1) &= -2 + 0.9 \cdot (0.75 \cdot v^0(1) + 0.25 \cdot v^0(2)) \\ v^0(2) &= -3 + 0.9 \cdot (0.25 \cdot v^0(1) + 0.75 \cdot v^0(2)) \end{aligned}$$

yields $v^0(1) = -24.12$ and $v^0(2) = -25.96$.

Step 3. We now seek an improving policy, $d_1(1)$ and $d_1(2)$, as follows

$$\max \left\{ \begin{array}{l} -2 + 0.9 \cdot (0.75 \cdot (-24.12) + 0.25 \cdot (-25.96)), \\ -0.5 + 0.9 \cdot (0.25 \cdot (-24.12) + 0.75 \cdot (-25.96)) \end{array} \right\} = \max\{-24.12, -23.45\}.$$

Hence $d_1(1) = 1$. Similarly,

$$\max \left\{ \begin{array}{l} -1 + 0.9 \cdot (0.75 \cdot (-24.12) + 0.25 \cdot (-25.96)), \\ -3 + 0.9 \cdot (0.25 \cdot (-24.12) + 0.75 \cdot (-25.96)) \end{array} \right\} = \max\{-23.12, -25.95\}$$

and $d_1(2) = 0$.

Step 4. Since $d_0(1) \neq d_1(1)$ and $d_0(2) \neq d_1(2)$, set $n = 1$ and return to the policy evaluation step.

Step 2. The solution of the linear system of equations for $d_1(1) = 1$ and $d_1(2) = 0$ yields $v^1(1) = -7.33$ and $v^1(2) = -7.67$.

Step 3. The new policy d_2 is found as follows

$$\max \left\{ \begin{array}{l} -2 + 0.9 \cdot (0.75 \cdot (-7.33) + 0.25 \cdot (-7.67)), \\ -0.5 + 0.9 \cdot (0.25 \cdot (-7.33) + 0.75 \cdot (-7.67)) \end{array} \right\} = \max\{-8.67, -7.33\}$$

and $d_2(1) = 1$. Similarly,

$$\max \left\{ \begin{array}{l} -1 + 0.9 \cdot (0.75 \cdot (-7.33) + 0.25 \cdot (-7.67)), \\ -3 + 0.9 \cdot (0.25 \cdot (-7.33) + 0.75 \cdot (-7.67)) \end{array} \right\} = \max\{-7.67, -9.83\}$$

PI: A NUMERICAL EXAMPLE

We illustrate the implementation of the PI algorithm with a small example. Consider a problem with 2 states and 2 actions, $S = \{1, 2\}$ and $A = \{0, 1\}$. Let the transition probabilities and the rewards be $p(1|1, 0) = 0.75$, $p(1|1, 1) = 0.25$, $p(2|1, 0) = 0.75$, $p(2|1, 1) = 0.25$, $r(1, 0) = -2$, $r(1, 1) = -0.5$, $r(2, 0) = -1$, and $r(2, 1) = -3$. We set $\lambda = 0.9$ and apply the policy iteration algorithm to this problem instance to find the optimal policy.

and $d_2(2) = 0$.

Step 4. Since $d_1(1) = d_2(1)$ and $d_1(2) = d_2(2)$, the algorithm terminates. The resulting optimal policy is $d^* = [1, 0]$ with value vector $v^* = [-7.33, -7.67]$.

MODIFIED PI ALGORITHM

As mentioned in the first section, for large state spaces the exact solution of the system of equations given by Equation (3) can be computationally prohibitive. The key idea behind the MPI algorithm is that it is not necessary to determine the value vector for the current policy precisely in order to identify an improving policy. Therefore, during policy evaluation, the MPI algorithm obtains an approximate solution to Equation (3) by using successive approximations with a fixed policy. That is, MPI combines

features of both policy iteration and value iteration. The reader can refer to the article titled ***Total Expected Discounted Reward MDPs: Value Iteration Algorithm*** in this encyclopedia for details. Like policy iteration, it contains an improvement and an evaluation step, but the evaluation step is iterative like the value iteration algorithm. It converges faster than value iteration and requires at least as many iterations as policy iteration. However, the computational effort per iteration exceeds that for value iteration and is less than that for policy iteration.

Modified PI Algorithm [3]

Let $\{m_n\}$ be a sequence of nonnegative integers.

1. Select $v_0 \in V$, $\epsilon > 0$, and set $n = 0$.
2. (Policy Improvement) Choose d_{n+1} to satisfy

$$d_{n+1} \in \operatorname{argmax}_{d \in D} \{r_d + \lambda P_d v^n\}$$

setting $d_{n+1} := d_n$ if possible (if $n > 0$).

3. (Partial Policy Evaluation) Obtain v^{n+1}
 - (a) Set $k = 0$ and

$$u_0^n = \max_{d \in D} \{r_d + \lambda P_d v^n\}.$$

- (b) If $\|u_0^n - v^n\| < \epsilon(1 - \lambda)/2\lambda$, go to Step 4. Otherwise go to (c).
 - (c) If $k = m_n$, go to (e). Otherwise compute u_{k+1}^n as follows

$$u_{k+1}^n = r_{d_{n+1}} + \lambda P_{d_{n+1}} u_k^n.$$

- (d) Set $k := k + 1$ and return to (c).
 - (e) Set $v^{n+1} := u_{m_n}^n$, $n := n + 1$, and go back to Step 2.
4. Return $d_\epsilon := d_{n+1}$.

The partial policy evaluation (Step 3) performs the substeps (c) and (d) for m_n iterations, where m_n may be

1. fixed for all iterations, that is, $m_n = m$ for all n ;
2. chosen according to some prespecified pattern, for example, m_n can be increasing in n ; or
3. selected adaptively, for example, $\|u^{m_n+1} - u^{m_n}\| < \epsilon_n$ where ϵ_n is fixed or variable [3].

If $m_n = 0$, then the MPI algorithm coincides with value iteration algorithm, and if $m_n = \infty$, then it coincides with the PI algorithm.

Since we partially evaluate policies in the MPI algorithm, the resulting policy is called ϵ -optimal. For a proof of convergence of the MPI algorithm and other variants of policy iteration (e.g., Gauss–Seidel, Jacobi, and/or overrelaxation) refer to Puterman [3].

MPI: A NUMERICAL EXAMPLE

For the example we solved using PI algorithm, now we consider the MPI algorithm using $m_n = 5 \forall n$, and $\epsilon = 0.01$. Setting $n = 0$, we select $v_0(1) = -25$ and $v_0(2) = -30$. Using v_0 , we implement policy improvement, obtain $d_1(1) = 0$ and $d_1(2) = 0$. Then we set $k = 0$, and implement partial policy evaluation (Step 3) for $m_n = 5 \forall n$. The result of each iteration is given in Table 1.

Then we improve the current policy (Step 2) and obtain $d_2(1) = 1$ and $d_2(2) = 0$. We continue in this manner and after 10 more iterations meet the stopping criteria resulting with no change in the last policy we had obtained. Table 2 tabulates u values obtained in the partial policy evaluation step for the last iteration. The last policy improvement step returns $d^*(1) = 1$ and $d^*(2) = 0$ with resulting $v^*(1) = -7.3290$ and $v^*(2) = -7.6739$.

SUMMARY AND FURTHER READING

Policy iteration is an algorithm used to find optimal policies for stationary, infinite horizon MDPs. Under certain conditions, it

Table 1. $u_k^0(s)$ Values for $s = 1, 2$.

$s \mid k$	0	1	2	3	4	5
1	-25.63	-24.84	-24.01	-23.26	-22.59	-22.01
2	-24.63	-23.31	-22.45	-21.75	-21.14	-20.61

Table 2. $u_k^{11}(s)$ Values for $s = 1, 2$.

$s \mid k$	0	1	2	3	4	5
1	-7.33	-7.33	-7.33	-7.33	-7.33	-7.33
2	-7.68	-7.68	-7.68	-7.67	-7.67	-7.67

can also be used under the undiscounted, expected total reward criterion, and the average reward criterion [3]. It proves to be effective in terms of its convergence properties, though it can entail some computational drawbacks with increasing problem size. However, these drawbacks can be alleviated by considering the MPI algorithm or another variant of the PI algorithm.

For a deeper understanding of the PI algorithm, refer to Bertsekas [7], Heyman and Sobel [8], or Ross [9]. Other applications of PI algorithm can be found in Meyn [10], which discusses the application of PI algorithm to MDPs with general state space, and in Hansen [11], which illustrates an improved PI algorithm for Partially Observable MDPs. Madani [12] and Tsitsiklis [13] discuss the complexity of PI algorithm and its convergence.

TOTAL EXPECTED DISCOUNTED REWARD MDPs: VALUE ITERATION ALGORITHM

THEOLOGOS BOUNTOURELIS
Department of Industrial
Engineering, University of
Pittsburgh, Pittsburgh,
Pennsylvania

INTRODUCTION

The field of Markov decision processes (MDP) concerns the modeling and solving of dynamic decision making problems under uncertainty. The field has received considerable attention and researchers have developed the theoretical and computational tools for the application of MDPs in many scientific areas. These include the scheduling and controlling of manufacturing systems [1], finance [2], and management problems [3].

An MDP can be a *discrete-time*, a *continuous-time*, or a *semi-Markov* problem. In this article we will focus on discrete time MDPs. The basic structure of a typical discrete MDP implementation involves a *decision maker* evolving in a *discrete state space* through the execution of a series of *actions*. Starting at an initial state, at time period $t = 0$ and at every consecutive period $t = 1, 2, 3, \dots$, the decision maker observes the current *state* and chooses to execute some action that will probabilistically lead to a next state. Furthermore, the decision maker experiences a transition cost expressed by some *cost function* that assigns a numerical payoff, often random, to each executed action. The task of the decision maker is to select a sequence of actions in order to minimize some objective function of the costs collected over a *time* N .

A typical discrete-time MDP problem usually falls into one of the three main categories depending on the choice of the objective function and the time horizon. It can be a (i) finite horizon, *total cost problem*, where the objective is to minimize the cumulative

cost over some finite time horizon; (ii) an infinite horizon, *discounted cost problem*, where the objective is to minimize the sum of discounted cost over an infinite time horizon; or (iii) an *average reward problem*, where the objective is to minimize the average reward collected over an infinite time horizon.

This article is concerned with infinite horizon, discounted problems, where the cost collected at each period t is discounted by a factor γ^t , where $\gamma \in (0, 1)$ is a scalar referred to as the *discount factor*. The discounted problem is perhaps the most analytically tractable and widely studied MDP problem with its foundations set in the 1960s [4–6]. By considering the sum of discounted costs, and under some assumptions on the cost function, the discounted problem is usually well defined. By applying the discount factor at every consecutive decision epoch, the decisions made earlier have a greater effect on the cumulative cost than the decisions made later in time. This modeling framework has been proven useful in many different contexts, for example, the planning of an investment where the present value of the future payoffs is a discounted cumulative reward, or, the evaluation and control of a system that, at every time step, may fail with probability γ .

The article is structured as follows: we first provide the notation and we formally state the total cost, discounted problem. Subsequently, we characterize the problem optimal policies, and state the value iteration algorithm. In the sequel, we provide with a numerical example that illustrates the application of the value iteration algorithm on a problem instance. Finally, we conclude with some discussion on the underlying assumptions, the enhanced versions of the presented algorithm, and provide the relevant references.

A FORMAL DEFINITION OF THE TOTAL COST, DISCOUNTED, INFINITE HORIZON PROBLEM

A total cost discounted MDP $\mathcal{M}$, is defined by a tuple $\mathcal{M} = (\mathcal{X}, \mathcal{A}, \mathcal{P}, g, \gamma)$, where

- $\mathcal{X}$ is a finite set of states.
- $\mathcal{A}$ is a set function, defined on $\mathcal{X}$ that maps each $x \in \mathcal{X}$ to the finite, nonempty *action* set $\mathcal{A}(x)$, comprising all the actions that can be executed by the decision maker at state x .
- $\mathcal{P}$ is a *transition function*, defined on $\mathcal{X} \times \bigcup_{x \in \mathcal{X}} \mathcal{A}(x)$, that associates with every state action pair (x, a) in this set as discrete probability distribution $p(x, \cdot; a)$. The support sets of the distributions $p(x, \cdot; a)$ are subsets of the state set $\mathcal{X}$.
- $g : \mathcal{S} \times \bigcup_{x \in \mathcal{X}} \mathcal{A}(x) \rightarrow \mathbb{R}$ is a cost function, that maps each pair (x, a) , $a \in \mathcal{A}(x)$, to a cost $g(x, a)$.
- Finally, γ is a positive scalar referred to as the *discount factor*.

The decision maker starts from an initial state x_0 at period $t = 0$, and at every consecutive period $t = 1, 2, 3, \dots$ it (i) observes the current state x_t , (ii) selects and executes an action $a \in \mathcal{A}(x_t)$, and (iii) accumulates a cost of $\gamma^t \cdot g(x_t, a)$. We define a *policy* to be a sequence of functions $\mu_t : \mathcal{X} \rightarrow \mathcal{A}$, $t = 0, 1, 2, \dots$ with $\mu_t(x) \in \mathcal{A}(x)$. In words, a policy is a sequence of action selection rules that for every time step and state will return an action to be executed by the decision maker. We will call a policy *stationary* if $\mu_t = \mu$, $t = 0, 1, 2, \dots$, that is, if the action selection rule is independent of time. As is seen later, there is always an optimal stationary policy, and for the rest of this article we restrict ourselves to the class of stationary policies.

We denote by Π the set of all stationary policies. *The decision maker's objective is to determine a policy π that minimizes the cumulative cost*

$$V_\pi(x_0) = E_\pi \left[\sum_{t=0}^{\infty} \gamma^t \cdot g(x_t, \pi(x_t)) \right], \quad (1)$$

where the expectation $E_\pi[\cdot]$ is taken over all the possible realizations of the policy π . The vector V_π will be referred to as the *value function*, or the *cost-to-go* vector of the policy π . For every state $x \in \mathcal{X}$ we define

$$V^*(x) = \inf_{\pi \in \Pi} V_\pi(x). \quad (2)$$

The vector V^* will be referred to as the *optimal value function* or the *optimal cost-to-go* vector and expresses the total expected cost of initiating the process at some state $x \in \mathcal{X}$, and following the optimal policy thereafter. Furthermore, we define the *optimal policy* as

$$\pi^*(x) = \arg \inf_{\pi \in \Pi} V_\pi(x). \quad (3)$$

In the next section we state the conditions that should be satisfied by an optimal policy.

OPTIMALITY EQUATIONS

First, we introduce an operator that will play a pivotal role in the characterization of the optimal policies and the development of the value iteration algorithm. For any function $V : \mathcal{X} \rightarrow \mathbb{R}$, we define the operator $TV : \mathcal{X} \rightarrow \mathbb{R}$, as

$$(TV)(x) = \min_{a \in \mathcal{A}(x)} \left\{ g(x, a) + \gamma \sum_{y \in \mathcal{X}} p(x, y; a) \cdot V(y) \right\}, \quad x \in \mathcal{X}. \quad (4)$$

Consider the set of equations defined by $V(x) = TV(x)$, $x \in \mathcal{X}$, where the quantities $V(x)$, $x \in \mathcal{X}$ are the unknown variables. This set of equations will be described as

$$TV = V, \quad (5)$$

and referred to as the *optimality equations* or the *Bellman equations*. Then, under the assumption of (i) a countable state space $\mathcal{X}$, and (ii) a bounded cost function $g(x, a)$, it can be shown [7] that

- the optimality equations have a unique solution;
- the optimal value function, V^* satisfies the optimality equations, that is,

$$V^*(x) = \min_{a \in \mathcal{A}(x)} \left\{ g(x, a) + \gamma \sum_{y \in \mathcal{X}} p(x, y; a) \cdot V^*(y) \right\}, \quad x \in \mathcal{X}, \quad (6)$$

and

- from the optimality equations we can derive stationary optimal policies. That is, a stationary policy π is optimal if and only if it attains the minimum in Bellman's equation, that is,

$$V^*(x) = g(x, \pi(x)) + \gamma \sum_{y \in \mathcal{X}} p(x, y; \pi(x)) \cdot V^*(y), \quad x \in \mathcal{X}. \quad (7)$$

After we established the existence and the characterization of optimal policies, we proceed to the development of an algorithmic tool to numerically obtain an approximation of the optimal value function and policy. In the next section we present the most known computational method for discounted problems, the value iteration algorithm.

THE VALUE ITERATION ALGORITHM

The value iteration algorithm is the most celebrated and easily implementable algorithm for solving discounted MDPs. Before we state the algorithm, we should first provide some intuition behind it. Let the compositions of the operator T be T^k , that is,

$$T^k V(x) = T^{k-1}(TV), \quad k = 1, 2, 3, \dots \quad (8)$$

The composition operator has an interesting interpretation. Consider the problem where the decision maker must select its actions over a horizon of k steps, and then experience a terminal cost given by the vector $\gamma^k V$. It should be intuitively clear that as $k \rightarrow \infty$, the effects of the terminal costs are diminished at a geometric rate of γ^k , and the calculated costs $T^k V_0$ should converge to the optimal value function, V^* . Indeed, it can be proved [8] that for any initial value vector V_0 , we have that

$$\lim_{k \rightarrow \infty} T^k V_0 = V^*. \quad (9)$$

The convergence of $T^k V_0$ to the optimal value function provides the basis of the value iteration algorithm that will be described, in its most basic form, in the sequel.

For any cost-to-go vector V , we define the norm $\|V\| = \sup_{x \in \mathcal{X}} |V(x)|$. Then, for any $\epsilon > 0$, we define an ϵ -optimal policy to be a policy with an expected performance that is ϵ close to the optimal, that is,

$$\|V_{\pi_\epsilon} - V^*\| < \epsilon. \quad (10)$$

Then, the following algorithm is called the *value iteration algorithm* [7] and returns an ϵ -optimal policy.

Value Iteration Algorithm

- Step 0: Select a vector V_0 , and choose an $\epsilon > 0$.
- Step 1: Set $n = 0$.
- Step 2: $V_{n+1} = TV_n$.
- Step 3: If $\|V_{n+1} - V_n\| \leq \epsilon(1 - \gamma)/2\gamma$ go to Step 4, else go Step 2.
- Step 4: Set $\pi_\epsilon(x) = \arg \min_{a \in \mathcal{A}(x)} \{g(x, a) + \gamma \sum_{y \in \mathcal{X}} p(x, y; a) \cdot V_{n+1}(y)\}$ and terminate.

Assuming the existence of an optimal solution, the value iteration algorithm can find an ϵ -optimal policy π_ϵ within a finite number of iterations. Furthermore, for the cost-to-go estimates V_{n+1} , we have

$$\|V_{n+1} - V^*\| < \epsilon/2. \quad (11)$$

Hence, by choosing an ϵ small enough, the algorithm terminates with a policy close to the optimal.

AN EXAMPLE

In this section, we report a computational study on a two-state discounted MDP instance that demonstrates the application of the value iteration algorithm presented in this article.

We consider a discounted MDP instance defined by the state space $\mathcal{X} = \{x_1, x_2\}$, an action set $\mathcal{A}(x_1) = \{a_{11}, a_{12}\}$, $\mathcal{A}(x_2) = \{a_{21}, a_{22}\}$ and transition probabilities $p(x_1, x_1; a_{11}) = 0.4$, $p(x_1, x_2; a_{11}) = 0.6$, $p(x_1, x_1; a_{12}) = 0.5$, $p(x_1, x_2; a_{12}) = 0.5$, $p(x_2, x_1; a_{21}) = 0.7$, $p(x_2, x_2; a_{21}) = 0.3$, $p(x_2, x_1; a_{22}) = 0.2$, and $p(x_2, x_2; a_{22}) = 0.8$. Furthermore, we consider the cost function $g(x_1, a_{11}) = 1.2$, $g(x_1, a_{12}) = 2.1$,

$g(x_2, a_{21}) = 1.5$, $g(x_2, a_{22}) = 1.1$, and a discount factor $\gamma = 0.9$.

The optimality equations are given by

$$\begin{aligned} V^*(x_1) &= \min_{a \in \{a_{11}, a_{12}\}} \left\{ g(x_1, a) + 0.9 \right. \\ &\quad \cdot \left. \sum_{y \in \{x_1, x_2\}} p(x_1, y; a) V^*(y) \right\} \\ V^*(x_2) &= \min_{a \in \{a_{21}, a_{22}\}} \left\{ g(x_2, a) + 0.9 \right. \\ &\quad \cdot \left. \sum_{y \in \{x_1, x_2\}} p(x_2, y; a) V^*(y) \right\}, \end{aligned}$$

and the optimal solution is given by $V^*(x_1) = 11.3415$ and $V^*(x_2) = 11.2195$.

We choose $\epsilon = 0.01$ and initialize $V_0(x_1) = V_0(x_2) = 0$. We expect the value iteration algorithm to return an approximate value vector, which is 0.005 close to the optimal. Indeed, the value iteration algorithm terminates after 72 iterations returning the value vector $V_{72}(x_1) = 11.3368$ and $V_{72}(x_2) = 11.2148$, for which $\|V_{72} - V^*\| = 0.0047$. The implied policy is given by $\pi_\epsilon(x_1) = a_{11}$ and $\pi_\epsilon(x_2) = a_{22}$.

DISCUSSION

The two sufficient conditions for the theoretical convergence of the value iteration algorithm are (i) a countable state space, and, (ii) a bounded cost function. In practice, the algorithm requires a tabular representation of the state space in order to store the value function updates. However, there is a wealth of MDP's with an infinite state space. Furthermore, there are problems with a finite state space but their size still prohibits the tabular representation of the value function. In such cases, the value iteration algorithm may still converge if one carefully designs value function approximation methods. Such methods include truncation techniques [9], where the decision maker updates a value function estimate for a finite subset of the state space. If the truncated problem is close enough to the original, the value iteration

algorithm converges. These value iteration variants are called *approximation value iteration algorithms*. On the other hand, the boundedness of the cost function is an assumption rather restrictive for problems with an infinite state space. It has been proven that the value iteration algorithm converges under more general conditions that allow unbounded cost functions with the first results appearing in Harrison [10] and Lippman [11]. For examples with truncated state spaces and unbounded cost functions, we refer the reader to Puterman [7].

An important measure of performance of the value iteration algorithm is its *convergence rate*, that is, the number of iterations required in order to obtain an ϵ -optimal policy. There are a number of value iteration algorithm variants that employ sophisticated value update routines, or *action elimination* routines, that is, eliminating early suboptimal actions, that demonstrate improved algorithmic performance. For example, the *Gauss-Seidel value iteration*, the *Jacobi value iteration*, the *action elimination value iteration*, and combinations of them are generally characterized by improved convergence rates for a variety of MDP problems. For an extensive discussion on the different value iteration variants, we refer the reader to Puterman [7], whereas for more recent developments we refer the reader to Herzberg [12,13], Shlakhter *et al.* [14], and the references therein.

Other methods for solving discounted MDPs include linear programming (LP) [15,16] and the *policy iteration* algorithm. The LP approach formulates the discounted problem as an equivalent LP with its optimal solution equal to the optimal value function. The policy iteration algorithm starts with an initial policy and, at each iteration, a new policy is constructed from the previous one with an improved cost-to-go vector. For an extensive discussion on these subjects we refer the reader to Puterman [7].

TOUR SCHEDULING AND ROSTERING IN SERVICE OPERATIONS

This article examines the process of scheduling individual workers to meet some form of time varying demand. This most often occurs in a service operation where the rate at which work presents itself varies significantly. Operations of this type include call centers, hospital emergency rooms, retail outlets, restaurants, and mail handling facilities.

In the *tour scheduling* process, the forecasted workload is converted into a schedule that specifies what shifts are to be staffed on each day by each employee over the course of a planning period, typically a week. The schedule is developed to meet the demand workload requirements at a minimum cost. The *rostering* process assigns the identified shifts to individual workers so as to best match individual preferences.

In this article, we first examine the problem of scheduling an inbound call center. This example illustrates the scheduling process and identifies some of the inherent issues involved in scheduling and rostering. We then discuss other environments where the same type of scheduling problems exist, and highlight some key differences in those environments.

A CALL CENTER EXAMPLE

A *call center* is a facility used to provide interactive communications with customers. In a call center, customer service representatives (CSRs), or agents, interact with customers over the telephone. A *contact center* extends

the notion of a call center to allow for other means of communication, including e-mails, faxes, and instant messages.

While call centers often deploy sophisticated telephony and computer equipment, and may require a large facility, the cost of the customer service agent is typically the most significant and controllable cost associated with call center operation [1]. Agent salaries typically account for 60–70% of the call center's total operating cost [2]. As such, effective capacity management is a critical success factor for efficient operations.

The workload presented to a call center, in terms of inbound calls, varies over the course of a week and over the course of a day. In order to efficiently staff the call center, the number of workers on duty must vary over the course of the week and the course of the day to match demand.

Call center managers are typically charged with providing a target level of overall service quality, most often specified based on some measure of caller wait time. The task of the call center manager is to develop a work schedule that assigns individual agents to work at specific time so as to achieve this service level goal at the lowest possible cost. In order to do this, call center managers must

- forecast the workload in terms of call volume;
- determine the number of agents required in each time period to meet the workload and achieve the service level target;
- package the agent level requirements into a set of shifts to which agents can be assigned;
- assign individual agents to tours taking into account the agent's availability and preferences.

Managers of small call centers may perform these tasks manually, but in most moderate to large call centers they receive automated support from a workforce management system (WMS).

SCHEDULING MODELS

The Two-Stage Scheduling Approach

Overview. The two-stage approach is a standard model for tour scheduling. In this approach, the staffing and scheduling decisions are made separately. Staffing requirements are developed based on the anticipated work in each time period. The staffing requirements are then used as an input to the scheduling model.

Staffing Requirements. The first step in the two-stage approach is to determine the staffing requirement, the number of workers required in each time period. Time periods are often 30 min in length, but in some cases 15 min intervals are used. In many environments, the number of workers required varies significantly over the course of the day.

In a call center, call volume tends to follow predictable patterns, with random variations superimposed. Consider daily call volumes shown in Fig. 1. In this call center, Mondays are in general the busiest day, Fridays are the slowest days, and the call center is closed on the weekends and holidays (such as Independence Day). The graph shows a 5-period moving average, which illustrates

that over the course of a week call volume is roughly constant with no clear trend up or down.

Seasonality also applies within the day. Consider the fairly common pattern illustrated in Fig. 2. Call volume grows throughout the morning, peaking in midmorning then dropping off in the late morning and slowing further over lunch. A second smaller peak occurs in the afternoon. Overnight volume tends to be low. Figure 2 represents a Monday; other days have similar but slightly different patterns.

Staffing requirements are determined using a queueing model, an analytical model that estimates key queue parameters such as waiting time, based on the rate at which calls arrive, the average length of calls, and the number of agents available to service those calls. Because queueing models typically require a steady rate of call arrivals, the *rate* at which calls arrive is usually assumed to be constant for each 30 min period. In the SIPP (Stationary Independent Period by Period) method, each 30 time period is analyzed independently of all other periods using the average call volume for that period as illustrated in Fig. 3.

Figure 1. Calls offered daily.

Figure 2. Average call volume.

Figure 3. Arrival rates under SIPP.

The call center typically has a service level target, or a more formal service level agreement (SLA), that specifies the level of service to be provided in each period. For example, the SLA may specify that the

average time on hold should be 30 s or less, or that 80% of calls should be answered within 15 s. The expected call volume and service level requirements are inputs to the queueing model and the number of agents

Figure 4. Minimum Agents required by 30 min period.

required per period is the output. Figure 4 graphically illustrates the output of the staffing requirements process.

Tour Scheduling. Once per period staffing requirements are defined, a tour schedule can be developed. The objective of the tour scheduling process is to determine the number of agents to assign to each possible schedule on each day so as to meet the minimum staffing requirements at the lowest possible cost. This implies minimizing the number of extra agents scheduled; that is, minimizing staffing above and beyond the minimum requirements.

A *shift* designates the specific time intervals, typically 30-min periods, during which an agent is on duty on a particular day. Consider the following simple example; a call center is open from 8:00 a.m. to 10:00 p.m., for a total of 28 half hour periods per day. Agents are scheduled to 9 h shifts, and breaks are not explicitly scheduled. A shift may start at any half hour period and lasts for 18 contiguous half hour periods. With these assumptions a total of 11 different shifts are possible, starting on each half from 8:00 a.m. to 1:00 p.m.

A schedule must further define the days of the week to be worked. Assume the call center is open seven days a week, but agents are only scheduled to work five days. Further assume that the scheduling policy is to give workers their two days off consecutively. This policy implies a total of seven different *day patterns*.

Given this relatively set of options, the scheduler has a total of 77 shift/pattern combinations ($11 \text{ shifts} \times 7 \text{ day patterns}$), which we will refer to as tours, to which agents can be assigned. The schedule covers 196 time periods ($28 \text{ half hour periods per day} \times 7 \text{ days}$). Here, we assume that each agent works the same shift every day. If this restriction is relaxed then the number of tours may increase significantly.

The Minimum Cost Schedule. Given a set of time phased staffing requirements (Fig. 4), a set of available shifts and a set of day patterns, the scheduling problem can now be formulated as an optimization problem—assign agents to tours so as to meet the minimum staffing requirements at the lowest cost. This problem can be formulated as an integer program, a linear optimization problem where

the decision variables can take on only integer values (See the section titled “Combinatorial Optimization/Integer Programming” in this encyclopedia). In this case, the decision variables are the number of agents to assign to each shift and day pattern, and since only whole agents can be assigned these numbers must be integers.

This model is an example of a *weighted set covering* problem. The basic formulation for solving this problem was first presented by George Dantzig in 1954 [3]. Dantzig looked at a similar problem, scheduling toll booth operators when the number of operators required was defined for each discrete time period.

In this model, a matrix is developed that maps tours to time periods. The matrix has I rows, one for every time period in the planning horizon (often a week), and J columns, one for each schedule (i.e., a shift and day pattern combination) to which an agent can be assigned. The cells in the matrix (denoted a_{ij}) are equal to 1 if the shift j is “on” in time period i and 0 otherwise. The cost associated with each schedule (denoted c_j) is a measure of the number of hours in the schedule. The decision variable (denoted x_j) specifies the number of agents assigned to each schedule j . The number of agents required in each period (denoted b_i) is the list of staffing levels defined in the staffing requirements step.

Mathematically, the model can be expressed as

$$\text{Minimize } \sum_{j \in J} c_j x_j$$

Subject to

$$\sum_{j \in J} a_{ij} x_j \geq b_i, x_j \geq 0, x_j \text{ integer } \forall i$$

This model seeks to minimize the number of agent/hours scheduled, subject to the constraint that the number of agents assigned in each period (found by summing up all the agents assigned to each schedule) must be greater than or equal to the number required in that period.

This model requires one decision variable for each tour a corresponding to the number of workers assigned, and one constraint for

each time period. For the example outlined above, the model would contain 77 integer decision variables and 196 constraints.

Flexible Scheduling and the Feasible Schedule Problem. While integer programs are in general difficult to solve, the model outlined above is reasonably sized and can be solved to optimality without much difficulty. However, changing a few assumptions in this model formulation can quickly result in a much larger model.

Changes that can increase the size of the model include

- *Hours of Operation.* Expanding the hours of operation of the call center; in particular, moving to a 24-h operation.
- *Shift Options.* Adding more shifts; in particular, creating a more flexible scheduling environment that includes different shift lengths and/or part-time options.
- *Breaks.* Factoring break time into the schedule; in particular, explicitly including meal and/or rest breaks in the schedule.
- *Variable Shifts.* Creating tours that include different shifts on different days.

The call center, we looked at previously, operated from 8:00 a.m. to 10:00 a.m. leading to 11 different shifts, one starting on each half hour from 8:00 a.m. to 1:00 p.m. If we allow for continuous operation (24 h a day), we have 48 possible shift patterns; one for each half hour of the day. The result is a more than fourfold increase in the number of shifts.

The number of feasible tours will also increase if more flexible scheduling options are introduced. In the example stated earlier, we scheduled each agent five days per week with consecutive days off. That led to five feasible day patterns. If we relax the consecutive days off requirement, the result is a total of 21 day patterns (calculated as a combination; 7 choose 5) and the result is a total of 1008 schedules.

Now assume that in addition to five 8 h shifts, the call center offers employees the

option of four 10 h shifts. This leads to 48 new shifts (one per half hour) and 35 day patterns (calculated as a combination; 7 choose 4.) The result is a total of 1680 schedules.

Now let us further assume that the call center allows for part-time workers. (Part-time staffing can be quite beneficial when trying to balance supply and demand.) Let us assume they allow for 8 h shifts 4 days a week. The result is another 1680 schedules.

So, if we assume we have a call center operating 24 h a day, 7 days a week (which has three basic scheduling options—five eights, four tens, and four eights), then agents can be assigned to any of 4368 schedules. The introduction of 24 h operation and moderately flexible scheduling has increased the number of integer decision variables from 77 to 4368.

The schedules described above do not explicitly account for breaks. Assume that the call center assigns agents to 9 h shifts, with a half hour lunch break and two 15 min coffee breaks. Further, assume that the call center wishes to explicitly schedule the lunch break, but not the rest breaks.

The call center may wish to have some flexibility in how breaks are scheduled. The shifts shown in Fig. 5 illustrate how adjusting when the lunch break occurs can lead to different schedules. If this flexibility is incorporated into the scheduling model, the

model has a total of 21,840 integer decision variables.

The simple model with 77 decision variables developed in the previous section has now expanded to a model with more than 21,000 decision variables. Introduction of additional flexibility, such as more part-time options, would increase this number further. The calculations shown above account only for lunch breaks not rest breaks. If the call center wanted to explicitly schedule the rest break, they would need to plan based on 15-min periods, and incorporate the rest break options. This would have the effect of doubling the number of time periods, and therefore the number of constraints. The number of decision variables would increase significantly, perhaps by an order of magnitude or more.

While adding staffing flexibility greatly increases the size and complexity of the scheduling problem, there are significant benefits. In call centers with large peaks and valleys in the demand profile, it is difficult to fit supply to demand without creating significant overcapacity in other periods. Scheduling flexibility, in particular the use of part-time workers, allows call centers to better shape supply to meet the demand curve and reduce the cost of service delivery [4].

The Complexity of Flexibility. The example discussed above shows that the number of

Figure 5. Example Shift Schedules with Breaks.

possible shifts, and therefore the number of integer variables in the optimization program can easily become very large. With explicit break scheduling, the number of decision variables can grow into the tens of thousands or more; test problems with millions of integer decision variables have been analyzed in the literature [5].

Integer programs are difficult (i.e., time consuming) to solve to optimality, and the amount of time and other computer resources required grows in a nonlinear fashion with problem size. Call center scheduling problems of practical size can easily become intractable; that is, solving the problem to proven optimality cannot be accomplished in a reasonable time frame. (See the sections titled “NP-hard Network Flow Problems” and/or “Combinatorial Optimization/Integer Programming” in this encyclopedia for a more detailed discussion of integer programming and complexity theory.)

Given the benefits of increased staffing flexibility, more staffing options are desirable from a cost control perspective. But, given the increased complexity of the optimization problem, staffing flexibility is undesirable from a computational perspective. Finding a balance between these competing goals has been an active area of research. Researchers have developed many approaches, most of which can be put into two basic categories.

- *Implicit Break Scheduling.* In this approach, the scheduling problem is conceptually split into two components. Schedules are first developed without breaks. Breaks are then scheduled and assigned to schedules.
- *Heuristic Solutions.* Heuristic algorithms are designed to find *good* solutions quickly, but usually cannot solve a problem to optimality.

Implicit Scheduling Models

A number of researchers have developed a modified formulation that includes an implicit definition of breaks. In the basic *implicit shift scheduling* approach, shifts are set up with no breaks, for a single day

(i.e., no breaks within a day or between days). A separate set of decision variables is established that specifies the number of employees who are on break during any given time period. Shifts and breaks are essentially established separately, although constraints are established to ensure that the breaks will fit into schedule break windows. After the optimization is complete, a relatively straightforward procedure can be used to assign breaks to individual shifts. In models where this formulation can be applied, the implicit formulation will solve much faster than the explicit set covering approach; requiring between 25% and 50% of the computer time required to solve the basic set covering model [6]. Other models have been developed that increase flexibility and may solve even faster [7,8].

Implicit scheduling models were later extended to *implicit tour scheduling* models which can be applied to 24×7 operations where employees are scheduled across multiple days [5]. This model solves the scheduling problem for a week when the days worked are continuous, and all shifts are the same length. Under the conditions, the model dramatically reduces the number of decision variables required and creates integer programs that are quite tractable.

Heuristic Solutions

A *heuristic* is a solution method that is designed to quickly find a solution that is “good” but not necessarily optimal (see the section titled “Heuristics and Meta-heuristics” in this encyclopedia). Heuristics have the advantage that they can often solve a problem much faster than a method that is guaranteed to solve the problem to optimality. A key disadvantage is that not only do they typically not solve the problem to optimality but they usually cannot provide a meaningful estimate of the optimality gap.

Given the potential size of staff scheduling problem and the issue of intractability, heuristics are often employed to solve the problem. Many types of heuristics can be applied to this problem. With one type of heuristic, the scheduling problem is still formulated as an integer program, but heuristics are used to either reduce the size of the

problem or to speed up the solution process. A second type of heuristic formulates the problem in a fundamentally different way. For the staff scheduling problem, this is most often done by formulating the problem as a discrete event simulation model and solving it using simulation-based optimization.

Integer Programming Heuristics. Given the inherent complexity of integer programs, the use of heuristics is fairly common (see the section titled “Heuristics and Meta-heuristics” in this encyclopedia). One viable approach is to formulate the integer programming (IP) model as defined above and then to apply a heuristic algorithm, such as a genetic algorithm or simulated annealing, to search for a good solution to the IP. The Lagrangian heuristic has often been used to solve set covering problems [9] (see *Relationship Among Benders, Dantzig–Wolfe, and Lagrangian Optimization*).

A second type of heuristic for solving the scheduling IP seeks to reduce the size of the problem by eliminating potential solutions. In this problem, a reasonable approach is to reduce the number of schedules that can be selected. A relatively simple method is to avoid explicit break scheduling, allowing supervisors to manage breaks off-line based on how conditions unfold over the course of the shift.

Another method for dealing with the large number of feasible schedules that can be assigned is to use some heuristic to reduce the set of available schedules to something much smaller. An example is presented in [10]. An initial set of 7,120 possible schedules is reduced to a *working set* of 100 or less using two different procedures; one that picks schedules that are the “most different,” and one that picks schedules at random. They find that scheduling against this small subset can yield solutions within a few agents of the optimal solution in much less time than required to solve the complete problem. They also find that for larger working subsets, a random selection performs nearly as well as the most different selection, and performs much faster.

Simulation-Based Heuristics. An alternate approach to solving the shift scheduling

problem is to use a discrete event simulation model (see *Introduction to Discrete-Event Simulation*). A simulation model generates and processes individual customers, calls in the case of a call center, according to the predefined probability distributions describing arrival rates, service durations, and other random factors. The simulation approach has the advantage of specifying a more realistic model of the operation; for example, by allowing for more realistic distributions of service times, varying and uncertain arrival rates, abandonment, and absenteeism.

Simulation models may be used to allow managers to evaluate policy or scheduling changes interactively. Saltzman and Mehrorta describe an application of simulation modeling to evaluate the impact that launching a priority support service would have on standard and priority customers in an IT support call center [11].

Another way to use simulation is to perform *simulation-based optimization*; a process whereby simulation is used to evaluate the schedule, and a search algorithm is used to look for better schedules (see the section titled “Simulation Optimization” in this encyclopedia). A drawback of simulation-based optimization is that it is in general impossible to determine if a solution is optimal. Instead of finding a known optimal solution, or a solution known to be within a specified percentage of optimal, the simulation optimization algorithm typically searches until it is unable to find a better solution for some designated length of time.

A common approach to simulation-based scheduling is to use an analytical method to create a rough cut schedule. The rough cut schedule is then evaluated using the simulation model. Changing the original schedule, often using randomized changes, generates new schedules, which can then be simulated. One approach uses a simple *greedy* heuristic to generate a first cut schedule for a call center with variable arrival rates [12]. A simulation model then searches for better schedules, evaluating similar schedules using a meta-heuristic search technique known as *variable neighborhood search* (VNS). Other metaheuristics include genetic algorithms,

simulated annealing or Tabu search (see the section titled “Heuristics and Metaheuristics” in this encyclopedia). Other models use simulation and cutting planes to develop a schedule for a call center where agents have different skill sets [13,14].

Joint Staffing Models

The basic set covering model splits staffing requirements and shift scheduling into two separate and distinct steps. Joint staffing models combine these two steps into a one optimization problem.

The basic set covering model implicitly makes several important assumptions that are relaxed in joint scheduling models. First, by taking as an input the number of agents required in every time period, the model implicitly assumes that service level requirements are strict in every interval. In call centers with short interval peaks (such as the call centers represented in Figs 2 and 4), staffing to satisfy the peak arrival rate may result in excess capacity in other periods. In response to this issue, some call centers seek to achieve their service level targets over an extended period; perhaps a day, week, or even a month. This is often referred to as a *global service constraint*.

A second issue is the implicit assumption that arrival *rates* are known prior to the scheduling process. While the standard queueing model used when setting staffing requirements assume that the time between call arrivals is random, the models assume the average rate at which those calls arrive is known. In many situations this is not the case, and arrivals are considered to be *doubly stochastic*; customers arrive randomly with an average rate that itself is random [15,16].

These limitations can be addressed in *joint staffing and scheduling models*; models that integrates the staffing requirement and the shift scheduling steps into one optimization problem. The simulation models discussed above are inherently joint staffing and scheduling models, but the approach can also be applied to optimization models [17,18]. Some models use a piecewise linear approximation to the service level curve; allowing for the calculation of a global service level

based on the per period staffing decision [19,20].

ROSTERING

The final step in the scheduling process is rostering. *Rostering* is the process of assigning individual agents to schedules defined in the shift scheduling process. The rostering process must consider employee preferences (e.g., I prefer to start after 10:00 a.m.), employee restrictions (e.g., I cannot work on Thursdays), management policies (e.g., all employees must work one weekend day a month), and potentially union or contract restrictions (e.g., agents must have two consecutive days off.)

While extremely important in practice, the rostering process has received limited attention in academic research, perhaps because the process is not one that has not traditionally been highly automated. The process used at New Brunswick Telephone (NBTEL) is described in Ref. 21, a case where an automated heuristic was used to improve the process. The article highlights the rostering process (referred to as the shift assignment problem in this article) and identifies many of the issues.

The input to the rostering process is the set of schedules defined in the shift scheduling process. The output is the assignment of specific individuals to all of the schedules. The objective of the process is to match employee preferences as closely as possible. Agent preferences are not all considered equal, and preferences are often evaluated relative to worker seniority with higher levels of seniority given first choice.

Agent preferences cover a range of attributes; for example, days worked per week, starting time, length of lunch break, specific days off, or length of shift. Agent preferences may be soft (e.g., I would prefer not to start before 8:00 a.m.), or hard (e.g., I cannot work on Sundays). An agent's skill level forms another hard constraint; agents cannot be assigned to shifts that require skills they do not possess.

In smaller call centers, agent preferences can be tracked by supervisors informally and

rostering can be done in a manual fashion. In larger call centers with hundreds or even thousands of agents, a manual process is not practical and call centers typically utilize an *agent self-service* module within the WMS.

The self-service module typically allows agents to indicate their hard constraints and express their preferences. An agent may, for example, indicate hours or days of the week for which they are unavailable. The system may be configured to forward this entry to a supervisor for confirmation. They may also enter a request to take a week of vacation into the WMS. The WMS may use a set of configurable rules to evaluate the request. The request may be denied, approved, or forwarded to a supervisor for evaluation and dispensation.

When it comes to shift assignment, assignments are often handled via a bidding process. Agents may use the self-service module to bid on schedules they find desirable. The WMS will typically utilize some rule set to attempt to meet agent preferences to the extent possible. Agent bids are often weighted based on agent seniority. The rules by which bids are evaluated are often complex, and a heuristic is used to balance multiple criterion (see the section titled “Heuristics for Multiple Objectives” in this encyclopedia). The heuristic used at NBTel is described in Ref. 21. The heuristic utilized at NBTel first tries to ensure that all schedules are assigned to a qualified agent; it then seeks to satisfy agent requests in order of seniority. If at the end of the run, shifts remain unassigned, the application performs a series of two and three way swaps to allocate these unassigned shifts seeking to ensure that a qualified agent is assigned to every scheduled shift.

Given the difficulty of expressing, much less satisfying agent preferences, the resulting assignments may not satisfy all agents’ desires. A common way to address this issue is for the WFM to provide automated support for a *shift swapping* process. Shift swapping is a process whereby two or more agents may agree to trade shifts. The WFM system may support this process in various ways. It may allow agents to view the detailed schedule to identify potential swaps. It may also provide automated workflow support for the

swapping process. For example, the system may allow one agent to request a swap with another agent, prompting a message to the effected agent. If that agent accepts the swap, a message may be sent to the supervisor seeking approval.

Real-Time Control

Service environments, in general, and call centers, in particular, are subject to significant uncertainty in both the demand for and supply of labor. Call center volume often varies significantly from forecast, and staff absenteeism is a common problem. The implication is there even a well developed schedule may prove inadequate when implemented.

Real-time control refers to the actions managers make during the course of the day to adjust capacity to better match realized demand. Real-time control actions can be short-lived changes that affect capacity for only a short period of time, such as rescheduling breaks, or longer-term changes that affect capacity for an hour or more, such as sending employees home, or calling in additional workers. An overview of real-time control, focused on the hospitality industry, is provided in Ref. 22. An overview of the literature associated with real-time schedule adjustments is provided in Ref. 23. In this article, the authors study the applicability of real-time control heuristics in the quick service restaurant industry.

When applied to call centers, much of the research on real-time control addresses the issue of when to take action, and focuses on determining when a statistically significant deviation from forecast has occurred [24,25]. Other papers focus on updating agent schedules [26].

Real-World Challenges

While a substantial body of academic research addresses the workforce scheduling problem, the literature often deals with models that are highly simplified versions of reality. Stated another way, workforce management application vendors, and call center managers face a reality far more complex than that addressed in the academic

literature. Assumptions made about the statistical distributions of call arrivals, talk times, and caller's willingness to wait are often inaccurate. Agents are heterogeneous with differing skills, productivities, and scheduling preferences. Agent absenteeism is a chronic problem in many call centers. Performing scheduling and rostering sequentially may create schedules that cannot be staffed given agent availability constraints. In many real-world applications, call center managers make substantial manual changes to system generated schedules.

There is a subset of the literature that attempts to quantify, and in some cases address, these complexities. Issues related to how statistical distributions in real-world call centers differ from those assumed in standard models are addressed in Ref. 16. The design of a commercial workforce management application is described in Ref. 27. A series of papers examine issues related to implementing call center solutions at L.L. Bean [28–31]. Heterogeneous agent skills and sophisticated skills based routing greatly complicate the agent scheduling problem, and while assumed away in many scheduling models, this is an area of active research (See Ref. 1 for a more detailed discussion.)

SCHEDULING AND ROSTERING IN OTHER ENVIRONMENTS

The bulk of this document looks at scheduling and rostering in call center environments. The techniques and models discussed here are also applicable to a range of other environments such as airline ticket counters, airline crews, hospitals, emergency services, restaurants, retail outlets, or mail facilities. The methods discussed here apply to any operation characterized by a time varying requirement for personnel. Ernst *et al.* give an overview of scheduling and rostering applications across a range of applications, highlighting some of the key issues that arise in various environments [9]. Call Centers are a common application for scheduling and rostering models, and as discussed in this article, call centers are characterized by

significant uncertainty in workload. Other notable application areas are listed below.

Transportation Systems

Scheduling and rostering is an important aspect of transportation systems, such as airlines. Many models have been developed to look at airline crew scheduling [9]. One important difference with airline models, in particular, is the spatial aspect of the models. Airline crew schedules are driven by point to point transportation links which move the crew from one location to another. Crews have home locations that they must eventually return to, and leaving a crew at a remote location creates an additional cost. Other transportation applications, such as bus systems, subways, and other public transport systems, are less focused on the starting and ending location of the crew as they tend to be confined to a narrow geographical area. Transportation scheduling staff requirements are also less uncertain and more controllable than those in a call center. The transportation schedule tends to drive the staff schedule.

Health Care

Many models have been developed to analyze staffing issues in health-care delivery, most notably nurse scheduling. Much of this work has focused on allocating weekday and weekend shift in accordance with work regulations. Another interesting aspect of health-care models is the ability to substitute higher skilled workers for lower skilled requirements; that is, assigning an Registered Nurse (RN) when only an Licensed practical nurse (LPN) is required.

Emergency Services

Staffing is an important issue in emergency services such as police, fire, or ambulance services. Spatial issues are also important in emergency services, in particular, ambulance services where the response time are critical and driven in large part by the distance between the incident and the responding crew. Ambulance services also create a demand profile that is highly uncertain.

Retail

Scheduling and rostering is an important characteristic in retail operations of all types. Retail scheduling applications tend to be similar to call center models, although staffing levels are often defined exogenously rather than via a queueing model approach.

TPZS APPLICATIONS: BLOTTO GAMES

ALAN R. WASHBURN
Operations Research Department,
Naval Postgraduate School,
Monterey, California

Blotto games are a type of TPZS game that is solvable without first making a list of all pure strategies. This property is important because it permits large games to be solved, much more so than if all pure strategies had to be listed. The class is named after an example given in Ref. 1 that will be referred to and solved below. In that example, a fictional Colonel Blotto has 4 units with which to attack an enemy who has only 3 units, the object being to capture as many of four forts as possible. Each side can secretly divide its units over the four forts, and Blotto will capture each fort if and only if he assigns strictly more units to it than his opponent. If we let $\mathbf{x} = (x_i)$ and $\mathbf{y} = (y_i)$ be Blotto's and his opponent's allocations to forts, then the two sides might choose $\mathbf{x} = (2, 1, 0, 1)$ and $\mathbf{y} = (0, 1, 2, 0)$, in which case Blotto would capture the first and fourth forts, but not the other two.

Blackett [2] defined Blotto games in general. In a general Blotto game, player 1 has f units that he secretly allocates to n areas, so $\sum_{k=1}^n x_k \leq f$, and similarly player 2 has g units, with $\sum_{k=1}^n y_k \leq g$. The utility to player 1 (hereafter the "payoff") is $\sum_{k=1}^n A_k(x_k, y_k)$, where $A_k()$ is an arbitrary function representing the payoff to player 1 in the i th area. Blotto games are zero-sum, so the payoff to player 2 is implicit. Usually $A_k(x_k, y_k)$ increases with x_k and decreases with y_k , in which case each player will optimally allocate all of his units. All n of the payoff functions are identical in the introductory example, but that need not be the case in general. The characterizing features of a Blotto game are therefore four as follows:

- there are given numbers of identical units available to each side, and each

side can allocate his units as he wishes among several areas;

- neither side knows the allocations of the other, except for the totals;
- the payoff in each area depends only on the two allocations to that area;
- the payoff in the game is a sum of the payoffs in each area.

There has also been some interest in games with these four features, but which are not necessarily TPZS. Such games are covered in the article titled **Allocation Games**, with potential applications to economics. Blotto games are thus a subset of allocation games.

APPLICATIONS

There are some political situations that closely resemble Blotto games. Consider the United States Electoral College, where the collected electors from the various states meet to elect a president. The states are the areas, the resource for each party (assume only two significant political parties) is money, and the electors in each state are committed to the party that spends the most in that state. Even putting aside its cynicism about voter behavior, there are still two significant difficulties in making such a political application. One is the sequential nature of actual political campaigns, where each party closely watches the activities of the other and adjusts spending accordingly. This is not in accordance with the second characterizing feature of a Blotto game. The other difficulty is with the payoff. Laslier and Picard [3] distinguish between the "plurality game" where the payoff is the number of electors won, and the "tournament game" where the payoff is 1 if more than half of the electors are won, or otherwise 0. The plurality game is a Blotto game, but the tournament game is not because its payoff function is not a sum. The tournament game therefore does not benefit from special solution techniques that apply only to Blotto games, and it is

not true that optimal plurality strategies can be transferred to tournaments. Unfortunately, it is the tournament game that most closely resembles reality. On account of such difficulties, we cannot as yet claim any persuasive application of Blotto games to democratic politics.

Most of the applications of Blotto games are in the field of defence. One important application has been to the defense of a group of targets (ICBM silos, military bases, cities, etc.) against ICBM attack (so player 1's resource is an ICBM inventory, or perhaps an inventory of reentry vehicles) using Anti Ballistic Missiles (ABMs) (so player 2's resource is a number of ABMs). The resulting mixed strategies for the opponents are usually called *preallocated* to emphasize that the allocations require no observations about the details of the attack or defense chosen by the other side. In the simplest case the ABMs allocated to a target counter any ICBMs allocated to that target on a one-for-one basis, and the target is killed if and only if x_k strictly exceeds y_k , as in the introductory example. More generally, $A_k(x_k, y_k)$ represents a kill probability, and the sum $A(\mathbf{x}, \mathbf{y})$ is "expected number of targets killed." The Sections 4.3 and 5.6 of Ref. 4 give a good summary of specific formulations and solutions as of 1972.

In formulating a game that is potentially a Blotto game, careful attention must be paid to questions of who knows what and when. It would be significant if Blotto were able to discover the allocations of his opponent before making his own, or if the opposite situation should favor his enemy. In the introductory example, Blotto would capture at least two forts in the former situation, or only one in the latter. The value of the Blotto game ($5/3$ in the introductory example, as we will show below) will be somewhere in between those extremes, and is the value we should seek when both sides can protect the secrecy of their allocations.

Imagine that you are the defensive player in a game where there are 100 targets that you have to defend with 100 ABMs. The offense has 200 ICBMs with which he plans to attack the targets, so you are outnumbered. Each ABM will surely kill the

ICBM against which it is committed, and each surviving ICBM will kill the target against which it is committed. How should you employ the ABMs? One strategy would be the "myopic" strategy of intercepting the first 100 ICBMs that you see. Against that strategy, the offense could sacrifice 100 ICBMs and then use the remaining 100 to attack each target once. All 100 targets would be lost, so there must be a better strategy for employing the ABMs. A much better strategy would be to first observe the distribution of attackers, and then completely defend the most lightly attacked targets until you run out of ABMs. Against that strategy, the offense can do no better than to attack every target with two ICBMs, so 50 targets will survive. However, you might not be able to make the required observations. You might not be able to determine each ICBM's chosen target early enough, or the offense might make a "dribble attack" where the ICBMs show up at different times. Either possibility would foil the plan and lead to fewer than 50 targets surviving. A different defensive possibility, much easier to implement, would be to intercept each ICBM with probability 0.5. That strategy is particularly attractive because you do not need to know an ICBM's target when deciding whether to intercept it, and the strategy works just as well against dribble attacks. If the offense knows that you are using it, he should attack each target with two ICBMs, and $(0.5)^2$ of the targets will survive (about 25). The number of surviving targets varies between 0 and 50, depending on the tactics employed and the command-and-control situation.

The Blotto defense in the above situation would preallocate a certain number of ABMs to each target, keeping the exact number secret so that the offense cannot pick on the lightly defended targets. To be precise, the Blotto solution in this case has the number of ABMs assigned to each target being equally likely to be 0, 1, or 2 (note that the expected number of ABMs at each target is 1, as the ABM supply dictates). Even if the offense knows that distribution, he cannot do better than to assign 2 ICBMs to every target, thereby killing $2/3$ of the targets, on

the average, so about 33.3 will survive. This is an improvement over simply intercepting each ICBM with probability 0.5. In fact this is the best you can do as long as you know nothing about the attack other than the fact that it totals 200, and can determine each ICBM's target before committing an ABM. It would be better, of course, if you knew exactly how all the ICBMs were distributed over targets before committing any ABM. In fact, the value of that information can be quantified since it raises the average number of targets savable from 33.3 to 50.

In the above example, one-third of the targets in the optimal defense has no ABMs allocated. The logic is solid, but the result can still be bitter if you are one of the abandoned targets. Indeed, a case can be made that the only morally defensible way of defending cities is the provably ineffective myopic strategy—how can you deliberately let an ICBM attack Boston when you still have ABMs left? This is but one example of some of the ugly tactical quandaries produced by the Cold War. No ICBM attack ever occurred, but it was (and still is) necessary to plan for the possibility in the face of such issues.

There are also some military applications in areas other than missile defense. For example, strategic nuclear submarines basically have the job of remaining undetected in peacetime, awaiting the fateful day when they receive orders to launch their weapons. Those submarines must receive orders to patrol in particular parts of the ocean. If one imagines that the ocean is partitioned into n cells, one can arrive at a Blotto game where f submarines are allocated to those cells with the object of having as many submarines as possible remain undetected, while a certain amount of search effort is allocated to the same cells by an opponent with the opposite motivation. Games where one side must choose a route and the other must setup an ambush can also be viewed as Blotto games, with the areas being road segments. All of these applications share the idea that each side secretly distributes a single resource over multiple areas.

SOLUTION TECHNIQUES FOR DISCRETE, SYMMETRIC BLOTTO GAMES

In this section, we assume that the allocations of both players must be nonnegative integers; that is, that the Blotto game is discrete. We also make the symmetry assumption that all of the functions $A_k()$, are identical, and refer to each of them as $A()$. The methodology described below is essentially that of Ref. 5.

The total number of nonnegative, integer vectors $\mathbf{x}$ that sum to f is $\binom{n+f-1}{f}$, the number of combinations of $n+f-1$ things taken f at a time. This number is 35 for Blotto in the introductory game, or 20 for his opponent, so that game could be solved as a 35×20 matrix game. However, it should be clear that the brute force technique that begins by first constructing a complete payoff matrix will not work for large games. If $n = f = 10$, for example, Blotto would have 92,378 distinct strategies, even if we count only those that consume all of his resources. We seek a solution method that does not require explicitly listing all possible strategies.

We begin by seeking a bound on the game value that Blotto can enforce. A mixed strategy for Blotto is a joint distribution over the allocations to all n of the areas. Because of symmetry, each area should have the same marginal distribution for the number of units allocated—call that distribution $\mathbf{u} = (u_0, \dots, u_f)$, and let $E(\mathbf{u}, j)$ be the expected payoff at the j th area when player 2 allocates j units to that area. Thus

$$E(\mathbf{u}, j) = \sum_{i=0}^f A(i, j) u_i.$$

If Blotto can select $\mathbf{u}$ so that $E(\mathbf{u}, j) \geq a - bj$ for all j , then, since there are n identical areas and a total of g/n units per area available to player 2, the total payoff per area will be at least $a - bg/n$. Blotto wants to maximize this quantity, as in linear program P1:

Program P1: maximize $a - bg/n$
subject to the constraints

$$\begin{aligned}
\sum_{i=0}^f A(i,j)u_i &\geq a - bj; j = 0, \dots, g \\
\sum_{i=0}^f iu_i &\leq f/n \\
\sum_{i=0}^f u_i &= 1 \\
b &\geq 0, \text{ and } u_i \geq 0; i = 0, \dots, f.
\end{aligned}$$

In program P1, the first set of constraints forces the objective function to have the desired meaning, as explained above, and the rest require that $\mathbf{u}$ be a probability distribution over the integers 0 through f with a mean of at most f/n . If that distribution applies to every area, Blotto's mean total use of units will be at most f , as required. Counting a and b , which together with $\mathbf{u}$ constitute the variables, P1 has $f + 3$ variables and $g + 3$ constraints, not counting the nonnegativity constraints on $\mathbf{u}$. Neither the number of variables nor the number of constraints depends on n except through ratios, an important property.

With one caveat, the solution of P1 constitutes a lower bound on the value of the game that Blotto can guarantee. The caveat is that $\mathbf{u}$ must be *playable*, by which we mean that there must be some joint distribution of allocations over all of the targets such that

- the marginal distribution of the number of units used is $\mathbf{u}$ at every target, and
- the total number of units used never exceeds f .

The potential difficulty here is that, while P1 requires that the total number of units used should never exceed f on the average, Blotto's allocation must exceed f with probability 0, which is a stricter requirement. We will return to this potential difficulty later.

Consider the application of this idea to the introductory example. In that example, $A(i,j)$ simply indicates whether i is greater than j , so $E(\mathbf{u},j) = u_{j+1} + \dots + u_f$, and $f/n = 1$. Upon solving P1, we find that $\mathbf{u} = (1/3, 1/3, 1/3, 0, 0)$ and that the lower

bound is $5/12$. If $\mathbf{u}$ is playable, then Blotto can guarantee to capture at least $4(5/12) = 5/3$ forts, on the average. A moment's reflection reveals that $\mathbf{u}$ is in fact playable in this case. Blotto can consider the four forts in two pairs, to each of which he assigns exactly 2 units. Within each pair, Blotto attacks the first fort with 0, 1, or 2 units, equally likely, assigning the rest of the 2 units to the other fort. In this way, Blotto can make the distribution of units at every fort be $\mathbf{u}$, while simultaneously using exactly 4 units in total. Since $\mathbf{u}$ is playable, the value of the game is at least $5/3$.

We could, of course, also consider the game from the viewpoint of Blotto's opponent, who wishes to minimize the total payoff by making a clever choice of $\mathbf{v}$, the marginal distribution of the number of units assigned to the typical area. Similar logic to Blotto's leads to linear program P2

Program P2: minimize $c + df/n$

subject to the constraints

$$\begin{aligned}
\sum_{j=0}^g A(i,j)v_j &\leq c + di; i = 0, \dots, f \\
\sum_{j=0}^g jv_j &\leq g/n \\
\sum_{j=0}^g v_j &= 1 \\
d &\geq 0, \text{ and } v_j \geq 0; j = 0, \dots, g.
\end{aligned}$$

The variables in P2 are $\mathbf{v}$, c , and d , totaling $g + 3$ in number because the vector $\mathbf{v}$ has $g + 1$ components. Any feasible solution of P2 guarantees that the payoff per area is at most $c + df/n$, and the objective of P2 is to minimize that quantity. As long as the resulting $\mathbf{v}$ is playable, player 2 can guarantee that the total payoff per area will not exceed $c + df/n$, on the average.

In the case of the introductory example, the solution of P2 is that the objective function is $5/12$, and $\mathbf{v} = (5/12, 5/12, 2/12, 0)$. One way of playing $\mathbf{v}$ is as follows:

- Consider the four forts in pairs. Flip a coin to decide whether the first pair

gets 1 or 2 units, and give the rest to the second pair.

- If a pair gets 1 unit, flip another coin to decide which fort gets it.
- If a pair gets 2 units, roll a die to decide whether the allocation should be (0,2), (1,1), or (2,0), equally likely.

This method will obviously always result in using exactly 3 units, as is required. It also results in the marginal distribution $\mathbf{v}$ for the number of units assigned to any fort. The probability that a fort gets 0 units, for example, is $(1/2)(1/2) + (1/2)(1/3) = 5/12 = v_0$. Since $\mathbf{v}$ is playable, Blotto's opponent can guarantee that the payoff per fort does not exceed $5/12$, which is equivalent to guaranteeing that Blotto cannot capture more than $5/3$ forts, on the average. Since we earlier showed that Blotto can guarantee to capture at least that many forts, we have discovered that the value of the game is exactly $5/3$, and we have done so without ever making a list of all the strategies available.

It is no coincidence that linear programs P1 and P2 have the same value in the introductory game. The two linear programs are duals of each other, so both must have the same optimized objective function, and in fact either of them can be solved in order to recover all of the variables of both programs. We can therefore identify an algorithm for solving any discrete, symmetric Blotto game.

1. Solve P1 and/or P2 to discover $\mathbf{u}$ and $\mathbf{v}$, as well as a possible game value.
2. Test whether $\mathbf{u}$ and $\mathbf{v}$ are playable.
3. If both $\mathbf{u}$ and $\mathbf{v}$ are playable, then playing them is optimal and the game has been (easily) solved.
4. If either $\mathbf{u}$ or $\mathbf{v}$ is not playable, find some other way of solving the game, perhaps brute force.

Unfortunately, step 2 is, in principle, nearly as hard as solving the game by brute force in the first place, since there is no known algorithm for testing playability that does not begin by listing all possible allocations. This is disappointing, but should not be overly so. Methods for playing a given

marginal distribution can sometimes be guessed, as in the introductory example, and there are also some more systematic methods for playing arbitrary marginal distributions [6, Section 6.2]. It is encouraging that play is easiest in large games, the very ones that are most difficult to solve by brute force. Consider a Blotto game that is similar to the introductory example, except that f, g , and n are each 3 times as large. Blotto must now assign 12 units to 12 forts. The number of possible allocations of 12 units to 12 forts is over a million, but P1 and P2 do not change at all when the problem is scaled up, since the high-numbered variables are 0 and the high-numbered constraints are inactive even when there are only four forts. Furthermore, it occurs that $12\mathbf{u}$ and $12\mathbf{v}$ are both vectors of integers, so either $\mathbf{u}$ or $\mathbf{v}$ can be played by labeling 12 balls with a number of units and then randomly distributing the balls to forts. The same marginal distributions could also be played by triply replicating the strategy used earlier with four forts, but the point is that things simplify in Blotto games when the number of areas n is large. Any marginal distribution whose components are integer multiples of $(1/n)$ can be played in this manner.

As a result of considerations such as those above, large Blotto games are frequently dealt with by simply assuming playability. The entirety of the analytic effort is then in solving either P1 or P2, whichever is more convenient. This achieves the goal of "solving" Blotto games using a technique that does not require listing all possible allocations. Beale and Heselden [5] opine that the Blotto game without the playability restriction may actually be an improved model of reality, since various realistic phenomena make it impossible to forecast constraint levels exactly.

The results of this section depend on the assumption that the n areas all have the same payoff function. A similar approach will work if the payoff functions differ, although the analytic effort required increases substantially. A linear program similar to P1 must be solved for each of the different payoff functions, and it may be necessary to solve this collection of programs several times to

closely approximate the game value. Details can be found in Refs. 5 and 6, Section 6.3.

CONTINUOUS BLOTTO GAMES

If the number of units is very large, or continuous in nature (e.g., water being allocated to fires), we can consider a Blotto game where the allocations are real numbers, rather than integers. The bad news is that we can no longer make use of discrete linear programs, but the good news is that the potential for analytic solutions emerges.

Consider again the symmetric case where all n areas have the same payoff function. We can again search for Blotto's optimal marginal distribution, but the notation must change to deal with the continuous nature of the allocations. Let X be a random variable that stands for Blotto's allocation to a typical area, and let $P(X \leq x) = F(x)$; that is, let $F(x)$ be the cumulative distribution function (CDF) of X . This CDF replaces the marginal $\mathbf{u}$ that we employed in the discrete case. If player 2 allocates y units to an area, then the expected payoff is $E(F, y) \equiv \int_0^f A(x, y) dF(x)$, and if $E(F, y) \geq a - by$ for $y \geq 0$, then Blotto can guarantee that the payoff per area is at most $a - bg/n$, as before. The problem of maximizing this bound is

Problem P3: maximize $a - bg/n$

subject to the constraints

$$E(F, y) \geq a - by; y \geq 0$$

$$\int_0^f x dF(x) \leq f/n$$

$$b \geq 0.$$

Here the integral constraint on $F()$ is that the average allocation must not exceed f/n —other constraints requiring that $F()$ actually be a CDF on the interval $[0, f]$ should also be understood. The Stieltjes notation is required for the integrals because optimal CDFs in Blotto games are frequently discontinuous. Although the optimization problem is potentially difficult because it involves the unknown function $F()$, it is still solvable in some cases.

The simplest case where P3 is solvable is the majority-rules case where $A(x, y)$ is 1 if x exceeds y , or otherwise 0. In that case, $E(F, y) = 1 - F(y)$, so the corresponding constraint in P1 requires $F(y) \leq 1 - a + by$. We therefore consider CDFs of the form

$$F(x) = \begin{cases} 0; & x < 0 \\ 1 - a + bx; & 0 \leq x \leq a/b \\ 1; & x > a/b. \end{cases}$$

Such CDFs describe an allocation that is 0 with probability $1 - a$, or otherwise uniformly distributed between 0 and a/b . The mean allocation for such distributions is $a^2/(2b)$, which we expect to equal f/n when $F()$ is optimal; that is, $b = a^2/(2(f/n))$. Substituting this into the objective, we find that a should be chosen to maximize the quantity $a - a^2g/(2f)$. Equating the derivative to 0, we find that $a = f/g$, which is optimal as long as it is smaller than 1 (parameter a cannot exceed 1 because that would make $F(0)$ negative). If $f/g \leq 1$, substituting our solution for a into the objective reveals that Blotto can guarantee a payoff of at least $f/(2g)$. If $f/g > 1$, Blotto can still guarantee an average payoff of $1 - g/(2f)$ by making $a = 1$. In summary, Blotto can guarantee a payoff per area of

$$\begin{cases} f/(2g) & \text{if } f \leq g \text{ by choosing } a = f/g, \\ 1 - g/(2f) & \text{if } f > g \text{ by choosing } a = 1. \end{cases}$$

By considering a similar problem for Blotto's opponent, we can show that the opponent can also guarantee the same payoff; that is, the game has been solved as long as playability questions are ignored. The side that has the most units is said to be "dominant." The dominant side uses a uniform marginal distribution in each area. The dominated side does the same thing, except that he first abandons enough areas to make a uniform distribution over the same interval feasible. For Blotto, the abandoned fraction is $1 - a$. If we apply this result to the ABM versus ICBM example considered above, but ignoring the integer constraints, we find that the fraction of the targets killed by the dominant attacker is $1 - 100/(400) = 0.75$. The fraction found earlier with integer constraints is $2/3$,

Figure 1. The fraction of targets killed versus the ratio of ICBMs to ABMs, when the ICBMs are imperfect.

smaller than 0.75 because the fact that the defense wins ties is significant. Analytic solutions are also available [7] for the case where the defenders are perfect, but the attackers are not. Figure 1 shows the fraction of targets killed by the attacker when an unintercepted attacker's kill probability is only $p < 1$, instead of 1 as assumed above. In that figure, $A \equiv -\ln(1-p)(f/n)$ and $D \equiv -\ln(1-p)(g/n)$, where $\ln()$ is the natural logarithm and n is as usual the number of areas. The upper curve in Fig. 1 is very close to the majority-rules game value derived above.

Majority-rules Blotto games with continuous allocations were considered by Borel [8] as early as 1921, including a demonstration of playability. See also Refs 9 and 10 for complete solutions of various continuous games of this type.

Another solvable class of Blotto games is those where $A(\mathbf{x}, \mathbf{y})$ is a concave function of $\mathbf{x}$ for all $\mathbf{y}$. For such games, it is known [6, Section 5.2] that player 1 can safely confine himself to pure strategies, so that the value of the game is $\min_{\mathbf{y}} \max_{\mathbf{x}} A(\mathbf{x}, \mathbf{y})$. While the resulting computational problem is still significant, it is at least simpler than solving a continuous game with mixed strategies. If $A(\mathbf{x}, \mathbf{y})$ is actually a *linear* function of $\mathbf{x}$ for each $\mathbf{y}$ (in which case it is automatically convex), then the problem of computing

$\max_{\mathbf{x}} A(\mathbf{x}, \mathbf{y})$ is a linear program. The dual of that program is a minimization problem, which can be combined with the minimization on $\mathbf{y}$ to produce one master minimization problem that can be solved with standard optimization packages. For an example of this technique, see Ref. 11. Similar conclusions hold if $A(\mathbf{x}, \mathbf{y})$ is a convex function of $\mathbf{y}$ for all $\mathbf{x}$.

If the payoff function is convex in $\mathbf{y}$ for all $\mathbf{x}$ and at the same time concave in $\mathbf{x}$ for all $\mathbf{y}$, then the Blotto game has a saddlepoint. Perhaps the simplest class of games where this is true are logistics games, which have a payoff function of the form $A(\mathbf{x}, \mathbf{y}) = \sum_{k=1}^n x_k f_k(y_k)$, where $f_k()$ is convex. This function is linear in $\mathbf{x}$, so the total resource of player 1 might as well be taken to be $f = 1$, in which case x_k can be interpreted as "the probability that player 1 chooses area k ." The payoff in area k is determined entirely by player 2, who is as usual subject to a constraint g in allocating $\mathbf{y}$. The areas might correspond to different routes for a convoy, with $\mathbf{y}$ being an allocation of interdiction resources of some kind to the underlying network. This application is responsible for the name of the class, but there are other possibilities. The areas might be opportunities for terrorists, with $f_k(y_k)$ being the payoff to the terrorists if player 2 spends y_k in defending against the k th attack opportunity. The areas could also

be places for player 1 to hide, with g being a total amount of search effort for player 2. Regardless of the interpretation, logistics games can be easily solved because player 2 is effectively designing against the worst case choice of player 1. The value of the game (v) and Player 2's optimal strategy can be recovered from

$$\begin{aligned} &\text{Problem P4: minimize } v \\ &\text{subject to } f_k(y_k) \leq v, \\ &\quad \sum_{k=1}^n y_k \leq g, \text{ and} \\ &\quad y_k \geq 0; 1 \leq k \leq n. \end{aligned}$$

Such problems are usually simple enough to solve in spreadsheets.

SUPPLY CHAIN TRACKING SYSTEM

Introduction to Tracking System

There is still a great deal of confusion on the terms involved in tracking systems. Very little attention has been paid to point out the differences among the various concepts of these systems. These concepts, however, are rather important, since they determine the objectives and functions of such systems. "Traceability" is a term often used as synonymous of tracking, and is defined as "the ability to trace the history, application, or location of that which is under consideration" [1], which is clearly related to the International Standard Organization definition "ability to trace the history, application or location of an entity by means of recorded identifications" (ISO 8402). In addition, according to McFarlane *et al.* [2], "Automated identification involves the automated extraction of the identity of an object" [2]. These definitions can let envisage the system's main function to provide visibility and traceability. The first term basically refers to the level of communication between the different nodes and agents in the supply

chain [3]. From the logistics perspective, it is considered as the transparent view of time, place, status, and content [4]. Or from the IT perspective, the ability to access or view relevant data or information as it is related to logistics and the supply chain as a whole [5]. From the latter we can infer one definition that fits the purpose of this document: A tracking system is an information system that captures current and/or past information on location, status, physical integrity, environment conditions, identity, or life cycle of moving objects. When this identification takes place in an automated way in order to provide tracking or tracing information, then it is understood as an Auto-ID system. This information could be used for collaborative decision making processes, or some other types of managerial or administrative processes. A tracking system is, in simple words, a supplier of such information.

Architecture

The tracking system architecture comprises three main layers: identification, capturing, and information exchange.

The identification layer focuses on registering information of the object for identification purposes. This information registration has activities such as writing, encoding, and decoding of the object information.

The capturing layer, in its turn focuses on retrieving the information stocked in the identification registry. Activities such as reading, decoding, and encoding object information form part of this layer.

The exchange layer takes care of storing, sharing, and exchanging specific information among the different agents and it also draws queries and documents such as certificate profiles and pedigrees.

As an example, we can clearly distinguish all the above layers in the architecture framework of an EPCglobal Standards Development Process shown in Fig. 1 [6].

There are some other architectural formats for tracking systems, as the one proposed by Cheung *et al.* [7]. They suggest

Figure 1. EPCglobal standards architectural framework [6].

a three-tier architecture with device, infrastructure, and application functions. Device tier is simply the first two layers of our previous architecture, which accounts for identification and capturing roles. Infrastructure, in turn, provides information, middleware, and discovery services. Finally, application tier provides value-added services to their users through software components (i.e., ERP and WMS).

TRACKING TECHNOLOGIES IN THE SUPPLY CHAIN

All tracking systems are made up of some basic components. These tools interact with each other to identify, register, modify, store, communicate, and emit specific and relevant information to the user, based on different technologies. As these technologies have been experiencing a wider and more global usage worldwide, even though they are more concentrated in developed countries due to their

labor-technology cost ratio in these regions, their use is also growing in current developing countries because of new international regulations and tendencies in global trade.

For operations research, tracking technologies could help leverage areas such as retailing, for example, tracking systems can help find customers' shopping behaviors at the store, or increase inventory management efficiency through an increase in inventory accuracy [8]. In product life cycle management, for example, by identifying products at the item level, there is an increased visibility that could be used to better control their entire life cycle [9]. Process optimization, for example, efficiencies in processes such as replenishment could be gained due to more precise and on time information gathered by tracking technologies [10].

In this section we have chosen a set of tracking technologies whose performance covers main functions of tracking systems such as identification, capturing, and

exchange information; and we summarize the most representative of these technologies.

Identification and Capturing Technology

These technologies are the link between the real-world and the information systems. Their main function falls in the identification and capturing layers of the tracking system architecture. They identify real objects and allow specific information to be electronically introduced in the tracking system.

Optical. Optical technologies capture data through the visual interaction of readers and labels and its main characteristic is the “line of sight” needed for reading. These technologies can read linear coded information as well as multidimensional coded information. Later we describe the most relevant.

Barcode. It is a linear binary code formed by lines and spaces (white lines) of varying thicknesses printed in different combinations. Its most common reading technologies are lasers and cameras [11]. Barcodes have been implemented in a wide variety of applications and environments in the supply chain. From all types of inventory control to check out processes in point of sales, currently barcode scanners rely on wireless data transferring to provide remote data capture through mobile devices such as cell phones, all based on barcodes [12].

GS1 128. The GS1 128 is a lineal barcode with a high density of information. It is an extension from numeric conventional barcodes such as EAN 13. The GS1 128 can include all the ASCII coding characters [13].

This code is modular, which means that we can add more information continuously. The barcode size is in direct relation to the quantity of information that it holds. For instance, for mass consumption, a code grouping ID, expiration date, and a six numerical characters describing lot number, will take up approximately 121-mm length and 164-mm width. The height will be always constant, which in this case is 33 mm.

Figure 2. Bidimensional barcode: PDF 417 Data-Matrix.

Bidimensional Coding. The 2D Technologies are usually squared or rectangular patterns of data codification. Given their increased code spatial density and code reliability capabilities, they are suitable for more challenging environments or conditions, such as smaller products or surfaces that are exposed to more deterioration due to product manipulation. Pharmaceutical industry is a good example of an implementation of this type of code [14].

There are two general categories based on coding type:

Coding by levels. It can be read by special bidimensional readers or CDD and laser readers with the help of special software to decode the information. The standard most often used in this technology is the PDF417.

Coding by matrix. It consists of a bidimensional matrix, is usually more compacted than a PDF417 code and can be read only by a bidimensional reader. The code mostly used is Datamatrix (Fig. 2).

The main advantage of bidimensional code is the capacity to codify vast amounts of information in a more reduced area. Bidimensional codes can codify approximately 2000 characters in a single label. Next we explain the two main types of bidimensional codes.

PDF-417. This code can store a maximum of 1850 alphanumeric characters (ASCII) or 1100 binary codes in a label with an area of 3 by 4.5 cm.

Mainly, PDF-417 is used in transport labels when the information has to be read although the system is not accessible. It is also used in inventory management or identification of cards. This technology incorporates “built-in redundancy,” property that enables the card been read although it is 60% damaged.

In addition PDF-417 has the capacity of storing graphics [15].

To read the PDF-417 code, apart from using bidimensional barcode readers, multipurpose scanners can be used, with specific software [16]. Conventional lineal barcodes readers are not useful. As all optical labels, PDF-417 has to be read with a direct "line sight" [17].

Datamatrix. Datamatrix is code in matrix form; it can store up to 2335 alphanumeric characters. The label is square shaped and it can extend from 0.0254 mm to 335.6 mm sideways. The size-information rate is approximately the following: the coding of 43 alphanumeric characters will be equivalent to a label of 4.2 mm sideways [18].

The Datamatrix codes are composed of squares modules placed within a pattern. This pattern consists of a frame which does not change and delimits the reading borderland; inside, the small modules are fully filled or completely blank to form a binary coding.

ECC200 is the last version of Datamatrix and has advanced coding algorithms error correction. This error correction algorithm enables that the codes damaged up to 60%, as in PDF-417, will be recognized. This version is widely being used in automobile, aerospace sector, electronics, semiconductor, medical devices, or in any case where product traceability is required. Because of the ability of Datamatrix to codify a large amount of data in a smaller code, it is being used in the cases where the reduced size of the product is a relevant factor [19].

The Datamatrix codes can be printed using most types of common thermal printers. Again, this optical symbol must also be read with a direct "line of sight."

The normative that defines this technology is ISO/IEC 16 022.

Radio Frequency. The radiofrequency technology is based on the use of radio frequencies for several purposes; these frequencies can be defined as wave oscillations within an entire radio spectrum range of 3 Hz to 300 GHz. In the supply chain environment, it is the base of contactless identification

systems without the need of line of sight. The range of frequencies where this technology is mostly used in supply chain starts from LF (low frequency) to a microwave, through HF (high frequency) and UHF (ultra high frequency). The minimum frequency used is 100 kHz while the maximum frequencies reach 2.4 GHz. The transmission frequency determinates the reading range and the ability of the signal to get over certain obstacles.

In the supply chain applications environment, there are different systems based on radio emissions, all of them have similar way of operation, but with a quite large number of possible applications such as asset and people tracking, product-user linkage, biometric measurements, product components tracking, retail operations, real-time inventories, and so on [20].

We next describe the main systems of radiofrequency that are mostly employed in supply chains.

RFID. The radiofrequency identification systems are the most known amongst the radiofrequency based systems. The first highlight is that these systems are oriented to information storage functions instead of exclusively transmitting, processing, or positioning of information/objects. RFID (radio frequency identification) is a formidable building block for an "internet of things," a network of electronically interrelated items that would allow companies to track goods through several simultaneous applications [21]. Their main function is as reflective transponders (mirror function). RFID are mainly based on two types of tags and their characteristic of a high area/reading rate. Tags can be classified into actives or passives depending on the type of the energy feed, which can be extern, (energy that tags get from the reader), or internal (energy provided by a battery incorporated in the tag). Passive tags do not have an internal power supply; thus they stay asleep until the moment they enter within a reader's range, using its energy to activate. Because of the high cost, size, and weight of the active tags, they are not considered as a good choice to be implemented in supply chains with

- 1.- A tag enters the RF field
- 2.- RF signal delivers energy to the tag
- 3.- The tag transmits data
- 4.- Antenna receives the data
- 5.- The reader receives and sends the data to the CPU
- 6.- CPU executes an action

Figure 3. RFID operation.

low cost products. Passive tags are usually incorporated in a paper label jointly with a barcode and other legible information.

RFID operations have three main stages: emission, information recovery, and reception, which are carried out by three elements such as reader, antenna, and tag (label that includes the relevant information from the identification) (Fig. 3). The basic operation is the following: the reader emits a signal through the antenna, in a specific frequency captured by the tag, then the tag modifies the signal appending the required information (data) to give it back to the reader. This system enables the communication between the composing elements (tag and reader), without the need of being in line of sight, but only in range. Thus, it is possible to read items that are inside a container (box, packages, etc.) without the need of opening it up. Hundreds of tags can be read *practically* at the same time in *proper* situations.

The characteristics of an RFID system are linked directly to the type of tag, and frequencies in which the system is performing. Frequency is a major determinant of the intensity of the radio waves, and thus, a key factor in performance levels and applications. RFID mainly performs operations in four frequency bands: LF, HF, UHF and MF (microwave frequency) [22].

In Table 1 we can see how this specification relates to the devices.

According to Information Access and Modification Capabilities, Tags can be classified as follows:

1. Read Only
2. Write Once Read Only (WORM)

3. Read Write
4. Read Write (with on board sensors)
5. Read Write (with integrated transmitters)

We can see tag classes in Table 2 and their advantages, disadvantages, and remarks in Table 3.

One final issue regarding RFID description is its need for standardization, in order to achieve ubiquitous deployment. Standardization must start with the information encoding within the tag, this is closely related to the aim of the information and thus, to the characteristics of the tags. An RFID class structure is proposed by the MIT Auto-ID Labs [23], which comprises five classes, starting with identity, higher functionality, semipassive, active ad hoc, and reader tags. Each successive class includes functionality of the previous classes.

RuBee. RuBee is a specific protocol of wireless transmission to send and receive (transceiver) little information packages (about 128 bytes). This protocol (IEEE P1902.1) is magnetic (inductive) and works in low frequencies (large wavelength in 131 kHz, about 2.5 km). The latter makes it a low consumer and, probably its most important characteristic, friendly to read through and around liquids and metals.

The RuBee protocol is similar to IEEE 802's, so it is more similar to Wi-Fi (IEEE 802.11), Bluetooth (IEEE 802.15), and Zigbee (802.15.4) [24] than to RFID. Another feature of the RuBee protocol is the signal decay. The range mostly varies from 8 to 10m volumetrically. This is because signal decay

Table 2. Tag Classes

Class	Known as		Memory		Power Source	Application	
0	EAS	EPC ^a	None	EPC	Passive	Antitheft	ID
1	EPC		Read only		Any	Identification	
2	EPC		Read write		Any	Data logging	
3	Sensor tags		Read write		Semipassive/active	Sensors	
4	Smart dust		Read write		Active	<i>Ad hoc</i> networking	

^aThe reaction on EPC standards evolution shows that the EPC class 0 is likely to evolve to a read write

Table 3. Comparison of Passive and Active tags [33]

Tag	Advantages	Disadvantages	Remarks
Passive	Longer life time Wider range of form factors Tags are more mechanically flexible Lowest cost	Distance limited to 4–5 m (UHF) Strictly controlled by local regulations	Most widely used in RFID applications Tags are LF, HF or UHF
Semi passive	Greater communication distance Can be used to manage other devices like sensors (temp, pressure etc.) Do not fall under the same strict power regulations imposed on passive devices	Expensive—due to battery and tag packaging Reliability—impossible to determinate whether a battery is good or bad, particularly in multiple transponder environments	Used mainly in real time system to track high value materials or equipment throughout a factory Tags are UHF
Active		Widespread proliferation of active transponders presents an environmental hazard from potentially toxic chemicals in battery	Used in logistics for tracking of containers on trains, trucks, etc. Tags are UHF or microwave

follows an $1/R^3$ behavior instead of a most common $1/R$, (Fig. 4) [25]. Tags designed for this technology offer a 64 bits storage capacity. They can also accept temperature, humidity, acceleration, and pressure sensors. There is, however, a cost for these advantages, because low frequencies have smaller bandwidths for data transfer, the reading rate per second is lower than in HF or UHF tags. Owing to this fact, applications for RuBee should not be focused on the passage of fast-moving tagged goods through control points [26].

Communication and Information Exchange

Communication in a tracking system can be performed by a variety of technologies; this

is the task of exchanging information in the form of data. This section presents a relevant subset of these technologies.

Wireless Sensor Networks. A Wireless Sensor Network (WSN) is defined as a network of transceivers, sensors, machine controllers, microcontrollers, and user interfaces with at least two nodes communicating by wireless ways [27].

The main WSN function is to provide the required information to smart environments; their responsibility is to “sense,” as well as to execute the first stages of data processing. The WSN is generally composed of two sub networks: data gathering and data distribution (Fig. 5) [28].

Figure 4. RuBee signal capture (low frequency) [25].

Figure 5. WSN [27].

The WSNs are composed of different spread nodes and each node is composed of sensors, microcontrollers, and radio emitters/receivers at the same time. This last point is where WSN and RFID converge to form a new technology. From this conjunction, the RFID tag is read, and the WSN uses the RFID tags as mobiles agents to enroute data. At the same time, the RFID tag uses the sensorial network to acquire data, it allows to identify and describe any specific

node in the network. A characteristic that enables the latter is that both WSN and, specifically, UHF RFID tags can work in the same ISM (*Industrial Scientific and Medical*) unlicensed frequency band [29], although WSN operates more commonly in 2.4 Ghz.

NFC (Near Field Communication). NFC is a standardized connectivity technology, wireless and short ranged, that enables

Figure 6. NFC system.

bidirectional interaction with electronic devices [30] in a simple and safety manner.

This technology has been developed from the combination of identification technologies (RFID) and contactless cards technology. NFC usually works in a frequency range of about 13.56 MHz, over an average distance of 1 dm. This technology is based on 18 092, 21 481, and ISO (*International Organization for Standardization*) standards; ECMA (European Association for Standardizing Information and Communication System) 340, 352 y 356 y ETSI TS 102, 190 [31].

NFC integrates both reading and writing components and a transponder in a single integrated circuit (chip). The different functions of this chip are controlled and triggered by means of software and combined with devices of individual use such as PDAs or mobile phones. The previous characteristic enables NFC devices perform as reading/writing or as an RFID tag. The main characteristic of the NFC is that it enables inter-connection between two available devices.

The benefits of this technology are found in the Mobile Systems:

- better use and a better user experience;
- easy access to services and physical objects content;
- access control;

- convenient exchange of digital items between devices;
- local payment capabilities and ticket issuing.

An NFC system involves different components divided mainly in three phases: data storage, processing, and application. (Fig. 6)

FFC (Far Field Communication). FFC is defined as the communication between the tag and the reader when takes place outside one full wavelength of range between them. This far field signal decays with the square of the distance from the antenna [32]. So, RFID systems that work on FFC (mainly UHF), have larger read range than those used in NFC (mainly LF and HF). Another characteristic of the FFC is that it is an electromagnetic wave radiation, rather than inductive as the NFC. The theoretical boundary between the two fields depends on the frequency used, and it is in fact directly proportional to $\lambda/2\pi$ where λ = wavelength [33]. This gives, for example, around 3.5 m for an HF system and 5 cm for UHF. NFC employs inductive coupling of the tag to the magnetic field circulating around the reader antenna (like a transformer), in its turn FFC uses similar techniques to radar (backscatter

Figure 7. NFC-FFC energy and information transferring system [33].

Table 4. Near and Far Field Performance Distances

Band	Near Field Region	Far Field Region
LF	<120 m	>12 km
HF	<1 m	>110 m
UHF	<1.65 cm	>1.65 m
Microwave	<0.25 cm	>0.25 cm

reflection) by coupling with the electric field [33] (Fig. 7).

From Table 4 we can see the differences on performing distances between NFC and FFC depending on bandwidth.

Positioning

Positioning systems are a set of technologies whose main function is the location of objects in a given space. These systems use the identification and capturing layers already mentioned in the architecture framework, and provide data to the third layer of information exchange. We next detail two specific positioning systems for indoor and outdoor usage.

Wi-Fi RTLS (Real Time Location System). The RTLS is a derivation of WSNs. This technology is essentially a tracking system based on Wi-Fi 802.11(x) whose main objective is to locate objects within its network coverage, which is usually for indoor location. The main advantages are that Wi-Fi

network keeps data and voice transference in addition to location information; in fact, this technology can track any wireless device such as PDA's, laptops, mobiles phone, or scanners, without the need of a tag.

The applications of this system are vast: assets tracking, process visibility, security, and so on [34].

There are several methods used in location tracking [35], the most used by RTLS are: cell, triangulation, and RF trace.

GPS. The Global Positioning System (GPS) is a constellation of satellites designed originally for military navigation. However, it has grown into a wide gamma of commercial applications comprising people's movement, goods and information, community building, environmental administration, weather and disaster forecasting, and emergency responses.

GPS works through the signals that satellites send to earth, where they are detected by mobile or stationary receiving devices, and therefore functions in outdoor environments. These signals are used to determinate the receiver's position in the planet surface with an average accuracy of decimeters, through a triangulation system called *oversimplification*.

Combined with geometric technologies and integrated with the reference space system, GPS data can be used to locate and trace vehicles and other objects, manage infrastructures, show time information and

Table 5. Characteristics and Applications of Reviewed Technologies

Standard	Technology	Characteristics	Applications
GS1 128	Optical (barcoding)	“Line of sight” needed for reading ASCII coding characters High density of information Coding by levels	Goods ID Supply chain traceability
PDF-417	Optical (bidimensional coding)	1850 ASCII characters coding “Built-inredundancy” Capacity of storing graphics Coding by matrix	Transport labels Inventory management Identification cards
Data matrix (ECC 200)	Optical (bidimensional coding)	2335 alphanumeric characters Reduced size Squares modules placed within a pattern Algorithms error correction	Automobile, aerospace sectors Electronics Medical devices
RFID (LF, HF, UHF and MF)	Radiofrequency	No need of line of sight Updating data Frequency determinates range Passive and active tags (power supply)	Goods ID Persons ID Supply chain traceability
RuBee	Radiofrequency	Implementation of sensors Little information packages transmission (about 128 bytes) Low frequencies (inductive coupling) Low consumer No problems with metals or liquids	Security Medical devices Agriculture
Wireless Sensor Network (WSN)	Communication	Nodes spread (microcontroller, transceiver and sensors) Sensors variety	Smart environments (agriculture, security hospital)
NFC	Communication	Short range (~1 decimeter) 13.56 MHz frequency Enables interconnection between two available devices	Contactless cards PDAs or mobile phones
FFC	Communication	Signal decays with the square of the distance from the antenna	Goods ID
Wi-Fi RTLS (real time location system)	Positioning	Derivation of WSN Data and voice transference in addition of location information Dell, triangulation, and RF trace localization methods	Electronic device tracking (laptops, mobile phones, etc.) Process visibility Security

Table 5. (Continued)

Standard	Technology	Characteristics	Applications
GPs	Positioning	Signals sent from satellites Signals have no cost to commercial or civilian use worldwide	Vehicles tracking Environmental administration Supply chain
SCIS (supply chain information systems)	Information	Management information systems (MIS) Decision support systems (DSS) and expert systems Advanced planning systems (APS) Enterprise resource planning (ERP) Forecasting/demands planning systems (DPS)	Supply chain management

images, and navigate between different points of the earth globe [36].

Normally we can find a minimum of 24 satellites any time in any part of the globe. Signals have no cost to commercial or civilian use worldwide.

In the supply chain, the more GPS-relevant applications are as follows:

- fleet activity tracing and movements;
- transaction validation by location and activity and delivery checking;
- verification and tracing of assets location;
- vehicles navigation to improve routing time.

Information

According to Hoffer *et al.* [37], data is: *'The stored representation of objects and events which have a meaning and importance in the user environment.'* Information, at its turn, may also be defined as *'The data which has been processed such that the knowledge of the person that uses these types of data is increased'* [38].

Using the above, we can define an Information System as an arrangement of people, data, process, and information technologies that interact together to gather, process, store, and provide information required to support an organization [39]. Nowadays,

virtually all state-of-the-art concepts of logistic and supply chain operations use information system and hence information technologies, such as management information systems (MIS), decision support systems (DSS), and expert systems.

According to ITAA (*Information Technology Association of America*), information technology is the technology that allows the capacity of capturing, processing, storing, emitting, transmitting, and receiving data and information in an electronic way, including texts, graphics, sound, and video just as well as the ability of controlling all kinds of machines electronically.

These technologies applied to the supply chain comprise a wide range of solutions. Among these solutions, we can highlight the APS (advanced planning systems), the ERP (enterprise resource planning), and the DPS (forecasting/demands planning systems).

All these solutions manage data, and the way it obtains data is the relation they have with tracking systems; after all, the first layer of a tracking system is data capturing, or bringing real item information into an informatics system in order to complete management processes.

CONCLUSIONS

As described previously, numerous Auto-ID technologies are available to enable

traceability of objects in the supply chain. Each one of these technological options provides traceability only for certain objects and is typically suitable only in a specific setting. RFID, for example, exhibits a large potential within warehouses and stores, but is less suitable for tracking goods in transit. A compendium of previously described technologies can be seen in Table 5. To achieve complete or at least more extensive traceability in a supply chain, different Auto-ID technologies need to be integrated across multiple locations and parties. Establishing traceability involves a significant investment not only into hardware and software, but also into building up the knowledge, expertise, and capability to effectively utilize these systems. Very often, implementation of (individual or integrated) Auto-ID solutions exceeds the financial and technological resources of most companies. This is one of the reasons it is highly needed to understand these technologies' true capabilities and shortcomings, and in addition to have clear guidelines for the design of a feasible and efficient tracking system.

Environmental Engineering, The
University of Texas, Austin, Texas

Networks are fundamental to the study of large-scale transportation models representing an entire metropolitan area, a state, or multistate regions. They can be applied in many contexts, including alternatives analysis, developing congestion pricing plans, identifying bottlenecks and critical infrastructure, shipping and freight logistics, multimodal planning, and disaster evacuation planning, to name only a few. The reason network models are so useful, and so broadly applicable, is because a mathematical network is a simple, compact, and flexible way to represent a large, complicated system.

This article provides an introduction to transportation network analysis, beginning with an overview of some basic network analysis problems, then describing different ways driver behavior can be represented on networks. Usually, the most important outputs of a network model are “link flows,” and the most important methods for finding these are provided next. Discussion then shifts to applications of network models, with emphases on congestion pricing and network design. The article concludes with a brief discussion of more advanced network models which may be suitable for particular applications, and a survey of important research works leading to the development of the ideas presented earlier.

Mathematically, a network consists of *links* and *nodes*. In transportation applications, a link usually represents a means of travel from one point to another: a road

segment between two intersections, a bus route between two stops, and so on, as seen in Fig. 1. The nodes, in turn, are the end points of the links. Quite often, nodes are adjacent to multiple links, so a node representing an intersection may adjoin multiple links representing road segments. Nodes and links may also be more abstract; for instance, nodes may represent “centroids” where trips begin and end, and links in a multimodal network might represent a transfer from one transport mode to another. The level of detail in a network varies from application to application. For multistate freight models, major highways may be the only links, and major cities the only nodes. For a city’s planning model, all major and minor arterials may be included as well. For a more detailed model, individual intersections may be “exploded” so that different links represent each turning movement (Fig. 2). A network is often compactly written as $G = (N, A)$ where N and A respectively represent the sets of nodes and links. A link is often written in terms of its end points, so (i, j) represents a link starting at node i and ending at node j .

TRANSPORTATION NETWORK PROBLEMS

The quintessential transportation network problem is *traffic assignment*, or translating demand for travel from all origins and destinations into *link flows* representing the number of travelers who use each link. This, in turn, can be used to create estimates of travel delay, air pollution, revenue on toll roads, and other factors which transportation planners consider when evaluating an alternative or a new policy. To represent travel demand, let $D \subseteq N \times N$ be a subset of ordered pairs (r, s) representing every combination of an origin r and destination s where there is demand for travel. We write the travel demand as d^{rs} for every $(r, s) \in D$.

Someone traveling from origin r to destination s will follow a sequence of adjacent

Figure 1. Physical transportation infrastructure (left) and network representation (right).

Figure 2. Two representations of the same intersection, with turning movements consolidated (a) and separated (b).

links $\{(r, i_1), (i_1, i_2), \dots, (i_k, s)\}$, called a *path*, and we write $(i, j) \in \pi$ to indicate that link (i, j) is part of path π . We write Π^{rs} to represent the set of all paths connecting origin r to destination s . The number of paths connecting an origin and destination can be very large, and grow exponentially with the size of the network. The good news is that we almost never need to list all of the elements of Π^{rs} in order to perform traffic assignment: the methods described later in this article

either generate only a small subset of all of the possible paths or work entirely with link flows, obviating the need to find *all* of the paths.

The goal of traffic assignment is to determine which links travelers will use, that is, to map the travel demands d^{rs} to the link flows x_{ij} . To do this, we need to specify two things: first, how travelers choose a path from an origin to a destination; and second, how travelers interact with each other. A common

assumption, described in more detail below, is that travelers want to choose a path which minimizes their travel time—that is, travel is not desirable in and of itself, but simply a means to move to a destination in order to conduct some more worthwhile activity. Because of congestion effects, however, the fastest path depends on the choices made by all of the other travelers. (A freeway may be very fast if few others choose to use it, but very slow if many others do.) This is commonly represented by a *link performance function* $t_{ij}(x_{ij})$ expressing the delay on link (i, j) as a function of the link flow x_{ij} . One common link performance function was developed by the Bureau of Public Roads, and is of the form

$$t_{ij}(x_{ij}) = t_{ij}^0 \left(1 + \alpha \left(\frac{x_{ij}}{c_{ij}} \right)^\beta \right),$$

where t_{ij}^0 is the free-flow travel time, c_{ij} the practical capacity,¹ and α and β shape parameters which can be calibrated. In the absence of field data, $\alpha = 0.15$ and $\beta = 4$ are common choices.

Traffic assignment is often used by itself, as planners seek to predict the impacts of various alternatives, such as construction of a new freeway or expanding capacity on existing roadways. However, it can also be used as a component of more sophisticated network models. For instance, tolls influence travelers route choices, and traffic assignment can be used to study the impact of different toll prices and identify the strategy providing maximum benefits to the region. Traffic assignment models can also be used in a prescriptive sense, rather than a descriptive one: instead of simply being used to evaluate a given set of alternatives, *network design models* aim to generate one or more alternatives which, if implemented, would provide the maximum benefit.

USER OPTIMAL AND SYSTEM OPTIMAL

The two most common rules for assigning travel demand to roadway links are to ensure that all trips follow shortest paths from the origin to the destination (called *user optimality*), or to assign demand so as to minimize the total travel time experienced by all travelers (called *system optimality*). User optimality can also be described as assigning demand in such a way that no single traveler can reduce his or her travel time by switching routes. User optimality is thought to be a better description of real traveler behavior, because travelers do not generally choose their route to minimize total congestion (nor would they know how to, even if so inclined). System optimality, while less realistic, is useful as a lower bound on congestion, for certain logistics problems, and, as described later, is central to certain congestion pricing problems. Although these rules are similar, in that assigning demand to shortest paths usually creates a low total congestion level, exceptions exist.

The most notable is the Braess paradox [2]. Consider the network in Fig. 3, where two routes connect a single origin and destination with $d = 6$, and the link performance functions are indicated on the figure.² By symmetry, the user optimal and system optimal flows are $x_{12} = x_{24} = x_{13} = x_{34} = 3$. These are indeed user optimal, because both routes have an equal and minimal travel time of 83 minutes, so no traveler has an incentive to change their decision. One can also verify that these flows are system optimal and that the total travel time is 498 vehicle-minutes, using the techniques mentioned later in the article.

Now, a new link (2, 3) is added to the network, with link performance function $t_{23}(x_{23}) = 10 + x_{23}$. Clearly, the new system optimal flows can have a minimal travel time no greater than 498 min, because the old flows still represent a valid traffic

¹The practical capacity roughly corresponds to the flow at LOS C, and is about 80% of the “true” capacity. See [1] for additional details.

²One may presume that the demand and flows are measured in some realistic units, such as hundreds or thousands of vehicles, rather than representing only six vehicles in total.

Figure 3. Network illustrating the Braess paradox.

assignment. However, the old flows are no longer user optimal: the new path has a travel time of 70 min, which is less than the other, used routes. Thus, travelers will shift onto the new path, and the new user optimum will result in equal usage of the three possible paths, resulting in link flows $x_{12} = x_{34} = 4$ and $x_{13} = x_{23} = x_{24} = 2$ and a travel time of 92 min on each path.

This should be surprising: by adding the link (2,3) the user optimal travel times *increased* for all travelers, with the total travel time increasing to 552 vehicle-min. Thus, adding capacity to the network actually degraded its performance! Whether this paradox is realistic, or just an artifact of modeling assumptions, has been debated for decades, and a full treatment is beyond the scope of this article. Still, the fact that it occurs at all shows that network models can behave counterintuitively, and justifies the existence of mathematically rigorous models and algorithms—engineering judgment alone can lead to highly faulty conclusions.

User optimal and system optimal link flows can also be represented as the solution to nonlinear optimization problems. For notational convenience, these optimization problems are expressed both in terms of the vector of path flows $\mathbf{h}$ and the vector of link flows $\mathbf{x}$, which are related by a constraint forcing consistency between these. User optimal link flows solve the program

$$\min_{\mathbf{x}, \mathbf{h}} \sum_{(i,j) \in A} \int_0^{x_{ij}} t_{ij}(x) dx \quad (1)$$

$$\text{s.t. } x_{ij} = \sum_{(r,s) \in D} \sum_{\pi \in \Pi^{rs}: (i,j) \in \pi} h^\pi \quad \forall (i,j) \in A \quad (2)$$

$$d^{rs} = \sum_{\pi \in \Pi^{rs}} h^\pi \quad \forall (r,s) \in D \quad (3)$$

$$h^\pi \geq 0 \quad \forall \pi \in \bigcup_{(r,s) \in D} \Pi^{rs} \quad (4)$$

while system optimal link flows solve

$$\min_{\mathbf{x}, \mathbf{h}} \sum_{(i,j) \in A} t_{ij}(x_{ij}) x_{ij} \quad (5)$$

$$\text{s.t. } x_{ij} = \sum_{(r,s) \in D} \sum_{\pi \in \Pi^{rs}: (i,j) \in \pi} h^\pi \quad \forall (i,j) \in A \quad (6)$$

$$d^{rs} = \sum_{\pi \in \Pi^{rs}} h^\pi \quad \forall (r,s) \in D \quad (7)$$

$$h^\pi \geq 0 \quad \forall \pi \in \bigcup_{(r,s) \in D} \Pi^{rs} \quad (8)$$

Notice that the constraints are the same for user optimal and system optimal assignment, reflecting the fact that a feasible solution to either problem is simply a way of assigning travel demand to the available paths and links: ensuring consistency between link flows and path flows with Equation (2) or (6); ensuring all demand is assigned with Equation (3) or (7); and ensuring nonnegativity of path flows with Equation (4) or Equation (8). The only difference between these two problems is their objective functions; that is, the decision rule for choosing one feasible traffic assignment over another.

It should be clear that the objective function (5) corresponds to system optimal flows; that Equation (1) corresponds to user optimal flows is less obvious. This can be seen by Lagrangianizing the constraints (3), introducing nonnegative dual variables κ , and writing the Karush–Kuhn–Tucker conditions for the resulting optimization

problem. After some simplification, these conditions include

$$\sum_{(i,j) \in \pi} t_{ij}(x_{ij}) \geq \kappa^{rs} \quad \forall (r,s) \in D, \pi \in \Pi^{rs} \quad (9)$$

$$h^\pi \left(\sum_{(i,j) \in \pi} t_{ij}(x_{ij}) - \kappa^{rs} \right) = 0 \quad \forall (r,s) \in D, \pi \in \Pi^{rs}. \quad (10)$$

Condition (9) implies $\kappa^{rs} = \min_{\pi \in \Pi^{rs}} \sum_{(i,j) \in \pi} t_{ij}(x_{ij})$, showing that κ^{rs} represents the travel time on the shortest path connecting origin r to destination s . Then, to satisfy the complementarity constraint (10), we either must have $\sum_{(i,j) \in \pi} t_{ij}(x_{ij}) = \kappa^{rs}$ (path π is a shortest path between r and s) or $h^\pi = 0$ (the path is unused). This is exactly the definition of user optimal flows.

Variational inequalities provide an alternate way of characterizing user optimal and system optimal flows. A vector of feasible path flows $\mathbf{h}^*$ is user optimal if and only if

$$\mathbf{F}(\mathbf{h}^*) \cdot (\mathbf{h} - \mathbf{h}^*) \geq 0 \quad (11)$$

for all feasible path flows $\mathbf{h}$, where $\mathbf{F}(\mathbf{h}^*)$ is the vector of path travel times.³ To understand this, notice that the condition can be rewritten as $\mathbf{F}(\mathbf{h}^*) \cdot \mathbf{h}^* \leq \mathbf{F}(\mathbf{h}^*) \cdot \mathbf{h}$ for all path flows $\mathbf{h}$. That is, no other path flow could reduce total system travel time *if path costs are fixed at their current levels*. If this were not true, then certainly some traveler could switch paths and reduce his or her travel time, so $\mathbf{h}^*$ cannot be user optimal. A similar variational inequality can be written for system optimal flows, replacing the path travel times with the marginal path travel times defined in the section titled “Congestion Pricing.”

At times, it is useful to express this variational inequality in terms of link flows, rather than path flows, as

$$\mathbf{t}(\mathbf{x}^*) \cdot (\mathbf{x} - \mathbf{x}^*) \geq 0 \quad (12)$$

for all feasible link flows $\mathbf{x}$, where $\mathbf{t}$ is the vector of link travel times. This can be derived

either as a transformation from Equation (11), or from the optimality conditions for the nonlinear program given by Equations (1)–(4). Variational inequality formulations are more flexible than nonlinear programming formulations. For instance, they can represent cases where the travel time on a link depends on the flow on other links as well. On the other hand, specialized algorithms for solving nonlinear programming formulations are usually faster than variational inequality-based formulations.

SOLVING FOR LINK FLOWS

Several approaches exist for finding user-optimal or system-optimal link flows, but all of them broadly follow the same iterative pattern, starting with any feasible assignment:

Path Loading. Given a set of feasible flows, calculate the travel times on each link.

Path Finding. Identify the optimal paths with respect to these travel times (shortest paths for user-optimal, and least marginal-cost paths, for system-optimal).

Path Adjusting. Shift some travelers from suboptimal paths onto optimal paths.

In this framework, the only difference between the user-optimal and system-optimal problems lies in the second step. Because system-optimal flows use least marginal cost paths, while user-optimal flows use least cost paths, the two assignment rules are fundamentally similar, and without loss of generality we only present algorithms for the user-optimal case. The third step requires the most care, because shifting too many travelers results in “over-correction” which does not converge toward equilibrium.

It is in this third step that most traffic assignment methods differ, in addition to the data structures used to represent the links or paths used by travelers at intermediate steps. Broadly speaking, solution methods can be classified as *link-based*, *path-based*, and *origin-based*.

Link-based methods do not actually store which paths travelers are using, and only

³That is, $F_\pi(\mathbf{h}^*) = \sum_{(i,j) \in \pi} t_{ij} \left(\sum_{\pi \ni (i,j)} h^\pi \right)$.

work with the aggregate link flows $\mathbf{x}$. Because of this, these algorithms are highly efficient in terms of computer memory, and were among the first practical traffic assignments developed. However, they are highly *inefficient* in terms of computation time, and, after making good progress in early iterations, usually bog down shortly thereafter and converge very slowly toward the final equilibrium.

The quintessential link-based method is the Frank–Wolfe algorithm, for which many variations and improvements have been proposed. The basic algorithm accomplishes path adjustment by first finding the optimal *all-or-nothing* link flow assignment with respect to the current travel times (that is, the link flows which would result from *all* travelers shifting onto the shortest path), and proportionately shifting link flows to make the current feasible assignment more closely resemble the all-or-nothing assignment. Mathematically, given a current feasible assignment $\mathbf{x}^0$ and an all-or-nothing assignment $\mathbf{x}^*$, the Frank–Wolfe algorithm seeks a flow on the line connecting these points, that is, a flow $(1 - \lambda)\mathbf{x}^0 + \lambda\mathbf{x}^*$ for $\lambda \in [0, 1]$, with λ chosen to minimize Equation (1) by a numerical line search method [3]. Thus, the Frank–Wolfe method can be summarized as

1. Start with feasible link flows $\mathbf{x}^0$, and set the iteration counter $k \leftarrow 0$.
2. Find the shortest paths between each origin and destination, with travel times $\mathbf{t}(\mathbf{x}^k)$.
3. Assign all trips to these shortest paths, obtaining an all-or-nothing flow vector $\mathbf{x}^*$.
4. Set $\mathbf{x}^{k+1} \leftarrow (1 - \lambda)\mathbf{x}^k + \lambda\mathbf{x}^*$, with $\lambda \in \arg \min_{\lambda \in [0, 1]} \sum_{(i, j) \in A} \int_0^{(1 - \lambda)x_{ij}^k + \lambda x_{ij}^*} t_{ij}(x) dx$.
5. Check convergence criterion. If satisfied, terminate. Otherwise, increment the iteration counter $k \leftarrow k + 1$ and return to Step 2.

Several convergence criteria are possible. The simplest option is to terminate the algorithm when the link flows change by a sufficiently small amount, that is, when $\|\mathbf{x}^{k+1} - \mathbf{x}^k\| < \epsilon_1$ for some predetermined ϵ_1 . This criterion is not recommended, as

it is unable to distinguish between true convergence and a scenario where a poorly-designed algorithm simply cannot find a good improvement over a nonequilibrium solution. A more theoretically sound option is to check consistency with the equilibrium principle itself. At equilibrium, all travelers are on shortest paths, so $\mathbf{t}(\mathbf{x}^*) \cdot \mathbf{x}^* = \mathbf{d} \cdot \boldsymbol{\kappa}$, with $\mathbf{d}$ and $\boldsymbol{\kappa}$ the vectors of travel demand and shortest path costs, respectively. Thus, one measure of equilibrium is the *relative gap*, defined by

$$\gamma = \frac{\mathbf{t}(\mathbf{x}) \cdot \mathbf{x}}{\mathbf{d} \cdot \boldsymbol{\kappa}} - 1$$

Note that this is zero if and only if all travelers are on shortest paths, that is, if and only if $\mathbf{x}$ is user optimal. Other definitions of relative gap exist in the literature and in commercial software, often involving the value of the objective function (1), but all share the common feature reaching zero only if equilibrium is reached.

As mentioned earlier, link-based methods are typically slow to converge. Better convergence can be seen with a *path-based* method, which tracks the paths used by individual origins and destinations, not just the aggregate link flows. Two notable path-based methods are *disaggregate simplicial decomposition* and *gradient projection*. The latter is simpler to explain, and functions as follows: the shortest path π_{rs}^* connecting each origin and destination $(r, s) \in D$ is identified, and declared the “basic” path, whose flow is defined as $h^{\pi_{rs}^*} = d_{rs} - \sum_{\pi \in \Pi^{rs}: \pi \neq \pi_{rs}^*} h^\pi$. Thus, the demand satisfaction constraint can simply be rewritten as $h^{\pi_{rs}^*} \geq 0$, so all of the constraints are captured through nonnegativity ($\mathbf{h} \geq 0$) and the only decision variables are the nonbasic path flows. With these decision variables, a descent direction for the path flows for origin-destination pair (r, s) can be identified as

$$\left[\kappa_{rs} - \sum_{(i, j) \in \pi_{rs}^*} t_{ij}(\mathbf{h}), \dots, \kappa_{rs} - \sum_{(i, j) \in \pi_{rs}^*} t_{ij}(\mathbf{h}) \right]$$

scaled by an appropriate factor. If this descent direction results in a step which

leaves the feasible region, a projection is performed to obtain the closest feasible point. Because the only constraints are nonnegativity, a projection is trivial, and simply consists of identifying a path with negative flow, and setting it to zero.

The steps of this algorithm can be summarized as

1. Start with feasible path flows $\mathbf{h}$ and a set of working paths $\hat{\Pi}^{rs} \leftarrow \{\pi \in \Pi^{rs} : h^\pi > 0\}$.
2. Find the shortest path π_{rs}^* between each origin and destination, with travel time κ_{rs} , and update the set of working paths $\hat{\Pi}^{rs} \leftarrow \hat{\Pi}^{rs} \cup \pi_{rs}^*$.
3. For each origin and destination (r, s) , and for each nonbasic path $\pi \in \hat{\Pi}^{rs} \setminus \pi_{rs}^*$ calculate the projected path flows $h^\pi \leftarrow \max \left\{ 0, h^\pi - \lambda_\pi \left(\sum_{(i,j) \in \pi} t_{ij}(\mathbf{h}) - \kappa_{rs} \right) \right\}$.
4. Update the basic path flows $h_{rs}^{\pi^*} = d_{rs} - \sum_{\pi \in \Pi^{rs} : \pi \neq \pi_{rs}^*} h^\pi$.
5. Check convergence criterion. If satisfied, terminate. Otherwise, return to Step 2.

Jayakrishnan *et al.* [4] report that a good step length is

$$\lambda_\pi = \left(\sum_{(i,j) \in (\pi \cup \pi^*) \cap (\pi \cap \pi^*)^C} \frac{dt_{ij}}{dx_{ij}}(\mathbf{h}) \right)^{-1}$$

Most recently, a class of *origin-based* (or *bush-based*) algorithms has arisen which seems to offer superior performance to both link-based and path-based methods in terms of convergence speed, with memory requirements in between the two. A *bush* (or *restricting subnetwork*) B_r , defined for each origin r , consists of all the arcs which travelers departing from that origin might plausibly use. Different algorithms use different definitions of “plausible,” but the general concept is that if an arc (i, j) is part of B_r , node j should be “farther away” from r than node i in some sense. This implies that B_r is acyclic, which makes it very easy to find shortest paths (and longest paths)

by scanning nodes in topological order. For each bush arc $(i, j) \in B_r$, an origin-based link flow x_{ij}^r is maintained, showing the number of travelers on (i, j) who departed from r . Clearly, $x_{ij} = \sum_r x_{ij}^r$.

The two steps which are iteratively performed are (i) bush equilibrating and (ii) bush updating. In the first step, the origin-based link flows x_{ij}^r are chosen so that they form an equilibrium on the bush B_r ; in the second, the bushes are updated, removing links which are unused, and adding new links which are now “plausible” for the origin r . Bar-Gera [5] uses a gradient projection approach, while Dial [6] shifts flow from longer paths to shorter ones; preliminary results seem to indicate that the latter approach is faster.

CONGESTION PRICING

That user-optimal and system-optimal traffic assignment are distinct suggests that effective transportation policy can reduce congestion and delay. Economically speaking, this distinction arises from congestion externalities—when a traveler drives on a congested link, he or she experiences delay equal to the travel time. However, this traveler’s presence adds to the congestion, causing a slight increase in delay to all of the other travelers behind him or her. The driver does *not* experience these costs and therefore, has no incentive to account for them. For system optimal link flows to result, these costs must be paid by the driver in some way.

In theory, congestion pricing can accomplish exactly this. Recall that optimality conditions for user-optimal assignment were

$$\sum_{(i,j) \in \pi} t_{ij}(x_{ij}) \geq \kappa^{rs} \quad \forall (r, s) \in D, \pi \in \Pi^{rs} \quad (13)$$

$$h^\pi \left(\sum_{(i,j) \in \pi} t_{ij}(x_{ij}) - \kappa^{rs} \right) = 0 \quad \forall (r, s) \in D, \pi \in \Pi^{rs} \quad (14)$$

Similar conditions can be written for the system-optimal problem:

$$\sum_{(i,j) \in \pi} \left[t_{ij}(x_{ij}) + x_{ij} \frac{dt_{ij}}{dx_{ij}}(x_{ij}) \right] \geq \kappa^{rs} \quad \forall (r,s) \in D, \pi \in \Pi^{rs}, \quad (15)$$

$$h^\pi \left(\sum_{(i,j) \in \pi} \left[t_{ij}(x_{ij}) + x_{ij} \frac{dt_{ij}}{dx_{ij}}(x_{ij}) \right] - \kappa^{rs} \right) = 0 \quad \forall (r,s) \in D, \pi \in \Pi^{rs}. \quad (16)$$

This implies that if a suitable toll, equal to $x_{ij} \frac{dt_{ij}}{dx_{ij}}(x_{ij})$, were added to each link, user-optimal flows would be identical to system-optimal flows. Note that this toll is in units of time; to convert to monetary units, we should multiply by a value of travel time (\$10/h is typical).

This toll has an intuitive explanation in terms of the congestion externalities mentioned above. The toll $x_{ij} \frac{dt_{ij}}{dx_{ij}}(x_{ij})$ is the product of the number of travelers on the link, and the marginal increase in travel time caused by another vehicle entering. Thus, charging this toll effectively eliminates this externality, bringing user optimal flows into alignment with system optimal ones.

This is called *first-best pricing* because it represents an idealized situation where a toll can be charged on every link (whether a freeway or a local street), without any regard to a maximum toll value. More realistic *second-best pricing* strategies take these practical limitations into account, but lack the simplicity and elegance of first-best pricing. An overview of second-best pricing strategies can be found in Small and Verhoef [7].

NETWORK DESIGN

Network design builds naturally on traffic assignment modeling. The network models described thus far treat the transport infrastructure as fixed, and the goal is to find path or link flows representing a certain behavior. Network design, by contrast, views the behavioral rule as fixed, and seeks a way of constructing or improving the infrastructure so as to maximize societal welfare. For

instance, one simple network design model is to make capacity improvements on certain links in order to decrease total system travel time, subject to a budget constraint. This can be formulated as

$$\begin{aligned} \min_{\mathbf{x}, \mathbf{h}, \kappa, \mathbf{y}} \quad & \sum_{(i,j) \in A} x_{ij} t_{ij}(x_{ij}, y_{ij}) \\ \text{s.t.} \quad & \sum_{(i,j) \in A} y_{ij} \leq B \\ & x_{ij} = \sum_{\pi \ni (i,j)} h^\pi \quad \forall (i,j) \in A \\ & \sum_{(i,j) \in \pi} t_{ij}(x_{ij}, y_{ij}) - \kappa^{rs} \geq 0 \quad \forall (r,s) \in D, \pi \in \Pi^{rs} \\ & h^\pi \left(\sum_{(i,j) \in \pi} t_{ij}(x_{ij}, y_{ij}) \kappa^{rs} \right) = 0 \quad \forall (r,s) \in D, \pi \in \Pi^{rs} \\ & \sum_{\pi \in \Pi^{rs}} h^\pi = d_{rs} \quad \forall (r,s) \in D \\ & h^\pi \geq 0 \quad \forall (r,s) \in D, \pi \in \Pi^{rs}. \end{aligned}$$

Here $\mathbf{y}$ represents the amount of money spent improving each link, and B the total budget available. Notice that the link travel times t_{ij} now depend both on the flow x_{ij} as well as the amount spent y_{ij} (perhaps representing increased capacity); and also notice that the user optimal first-order conditions are included as constraints.

As formulated, this is a mathematical program with equilibrium constraints, a class of optimization problems known to be difficult to solve due to nonconvexity of the feasible region. This can also be reformulated as a bilevel optimization problem, which again is nontrivial to solve. Thus, unlike the traffic assignment models described above, one cannot generally hope to solve network design problems exactly, let alone with an efficient algorithm. Instead, solution techniques for network design problems are heuristic in nature.

ADVANCED NETWORK MODELS

Although the models presented earlier in this article demonstrate the fundamental principles behind network models, they often lack realism in several important ways. Over the past decades, researchers have developed a number of more sophisticated extensions to these models, building on similar principles but relaxing simplifying assumptions. The remainder of this article provides a brief overview of these more advanced models. Stochastic user equilibrium relaxes the assumption that users accurately perceive travel times; elastic demand relaxes the assumption that travel demand is independent of travel cost; uncertain travel times relax the assumption that link performance functions are the same at all times; and dynamic traffic assignment relaxes the assumption of steady-state congestion and travel demand.

Stochastic User Equilibrium

One assumption made above is that users correctly perceive travel times, with unlimited precision. That is, given two routes, one with a travel time of exactly 11 min, and another with a travel time of 11 min and one sec, every traveler would choose the former. In reality, most travelers would be unable to distinguish between these trip lengths, and even if they could, would likely be indifferent between the two. The stochastic equilibrium framework accounts for this by introducing a random error term $\tilde{\epsilon}$ to users' perception of travel time. That is, the travel time $\tilde{u}_i^\pi$ user i perceives on path π is related to the true travel time $t_\pi(\mathbf{x})$ by

$$\tilde{u}_i^\pi(\mathbf{x}) = t_\pi(\mathbf{x}) + \tilde{\epsilon}_i^\pi.$$

Traveler i then picks the path available to him or her with minimal perceived travel time; this may or may not be the path with the lowest actual travel time. Typically, one assumes that these perceptions are unbiased, that is, that the expected value of $\tilde{\epsilon}$ is zero. If one further assumes that the $\tilde{\epsilon}$ are independent, identically distributed Gumbel random variables, this results in a logit route choice model, where the probability that traveler

i (traveling from origin r to destination s) chooses path π is given by

$$\Pr(\tilde{u}_i^\pi = \min_{\rho \in \Pi^{rs}} \{\tilde{u}_i^\rho\}) = \frac{e^{-\theta t_\pi}}{\sum_{\rho \in \Pi^{rs}} e^{-\theta t_\rho}}.$$

The parameter θ can be seen as the degree of accuracy in users' perceptions. If $\theta = 0$, users' perceptions are completely inaccurate, so every path is equally likely to be chosen regardless of its travel time. On the other hand, as $\theta \rightarrow \infty$, the user will almost certainly choose the path whose actual travel time is minimal. Thus, if there are d^{rs} travelers departing origin r for destination s , the path flows are given by

$$h^\pi = d^{rs} \frac{e^{-\theta t_\pi}}{\sum_{\rho \in \Pi^{rs}} e^{-\theta t_\rho}}$$

One can show that, under stochastic user equilibrium, the optimal link flows satisfy

$$\begin{aligned} \min_{\mathbf{x}, \mathbf{h}} \quad & \sum_{(i,j) \in A} \left(x_{ij} t_{ij}(x_{ij}) - \int_0^{x_{ij}} t_{ij}(x) dx \right) \\ & - \sum_{(r,s) \in D} d_{rs} E \left[\min_{\pi \in \Pi^{rs}} \{\tilde{u}_i^\pi(\mathbf{x})\} \right] \\ \text{s.t.} \quad & x_{ij} = \sum_{(r,s) \in D} \sum_{\pi \in \Pi^{rs}: (i,j) \in \pi} h^\pi \quad \forall (i,j) \in A \\ & d^{rs} = \sum_{\pi \in \Pi^{rs}} h^\pi \quad \forall (r,s) \in D \\ & h^\pi \geq 0 \quad \forall \pi \in \bigcup_{(r,s) \in D} \Pi^{rs}. \end{aligned}$$

Returning to the original example at hand, if two paths have a very similar travel time, to the extent that the perception error $\tilde{\epsilon}$ is substantially larger than the difference in true travel times, the stochastic user equilibrium model predicts nearly equal usages for the two paths, which is in accordance with intuition. Further details on stochastic user equilibrium, including proof that the above nonlinear program correctly assigns link flows and discussion on some limitations, can be found in Sheffi [8].

Elastic Demand

The demand for travel is not independent of travel costs—if congestion worsens, or if

an onerous toll is levied, travel demand will drop as users switch modes or activities, or simply reduce the number of optional trips made. A general way to represent this elasticity is to make the travel demand vector $\mathbf{d}$ a function of the trip travel times and tolls (simultaneously represented with the generalized cost κ), that is, $d_{rs} = S(\kappa_{rs})$ for some strictly decreasing (and thus invertible) function S . In this context, we seek a traffic assignment which forms a “fixed point” with respect to the demand functions and cost functions. That is, user path choices determine the travel costs between origins and destinations, which determine the demand for travel, which in turn determine the path choices. A fixed point of user path choices is consistent in this manner.

One way to formulate the user optimal problem with elastic demand is with the non-linear program

$$\begin{aligned} \min_{\mathbf{x}, \mathbf{h}} \quad & \sum_{(i,j) \in A} \int_0^{x_{ij}} t_{ij}(x) dx \\ & - \sum_{(r,s) \in D} \int_0^{d_{rs}} S_{rs}^{-1}(s) ds \\ \text{s.t.} \quad & x_{ij} = \sum_{(r,s) \in D} \sum_{\pi \in \Pi^{rs}: (i,j) \in \pi} h^\pi \quad \forall (i,j) \in A \\ & d_{rs} = \sum_{\pi \in \Pi^{rs}} h^\pi \quad \forall (r,s) \in D \\ & h^\pi \geq 0 \quad \forall \pi \in \bigcup_{(r,s) \in D} \Pi^{rs} \\ & d_{rs} \geq 0 \quad \forall (r,s) \in D \end{aligned} \quad (17)$$

$$d_{rs} = \sum_{\pi \in \Pi^{rs}} h^\pi \quad \forall (r,s) \in D \quad (18)$$

$$h^\pi \geq 0 \quad \forall \pi \in \bigcup_{(r,s) \in D} \Pi^{rs} \quad (19)$$

$$d_{rs} \geq 0 \quad \forall (r,s) \in D \quad (20)$$

To verify this, the first-order conditions include

$$\sum_{(i,j) \in \pi} t_{ij}(x_{ij}) \geq \kappa^{rs} \quad \forall (r,s) \in D, \pi \in \Pi^{rs} \quad (21)$$

$$\begin{aligned} h^\pi \left(\sum_{(i,j) \in \pi} t_{ij}(x_{ij}) - \kappa^{rs} \right) &= 0 \\ \forall (r,s) \in D, \pi \in \Pi^{rs} \end{aligned} \quad (22)$$

$$\kappa_{rs} \geq S_{rs}^{-1}(d_{rs}) \quad \forall (r,s) \in D \quad (23)$$

$$d_{rs}(\kappa_{rs} - S_{rs}^{-1}(d_{rs})) = 0 \quad \forall (r,s) \in D. \quad (24)$$

As before, conditions (22) and (23) enforce user optimality. The remaining conditions enforce that the travel demand is correct, given the shortest path costs between each origin and destination. To see this, note that Equation (25) requires $\kappa_{rs} = S_{rs}^{-1}(d_{rs})$ if $d_{rs} > 0$, that is, if there is positive demand from an origin to a destination, we must have $d_{rs} = S(\kappa_{rs})$. On the other hand, if the demand is zero, condition (24) allows the possibility of $d_{rs} > S(\kappa_{rs})$, as would happen if $S(\kappa_{rs}) < 0$.

Often, the elastic demand problem can be solved by introducing artificial “dummy arcs” to the network representing unsatisfied demand. If an upper bound $\bar{d}_{rs}$ on the demand between each origin and destination is defined, one can create new arcs connecting each origin to each destination, with a cost function $t_{rs} = S_{rs}^{-1}(\bar{d}_{rs} - x_{rs})$. Solving a fixed demand problem on this network (with demand for travel from each origin to each destination set at the upper bound) now produces an answer to the elastic demand problem: at equilibrium, the direct arc connecting origin r to destination s has the cost κ_{rs} (as does every other used path) and thus its flow is $x_{rs} = \bar{d}_{rs} - S(\kappa_{rs})$, which is exactly the unsatisfied demand.

Uncertain Costs

The assumption that travel times can be known with certainty limits network modelers’ ability to consider events such as incidents or poor weather, as well as their ability to evaluate innovative technologies such as traveler information systems (which are only valuable because conditions cannot be accurately predicted in advance). Furthermore, when users receive information *en route*, they may choose to change their path. This leads to the concept of *on-line routing*, where the full travel path is unknown at the start of the trip, and depends on the information received along the way. The decision rule which associates a particular path with information is known as a *policy* or *hyperpath*, and can be written as $\pi_i(\theta)$ to represent the choice made when information θ is provided at node i . This description is somewhat vague in recognition of the diversity of approaches researchers have brought to modeling information and

uncertainty; more rigorous derivation for specific problem assumptions can be found in the references that follow.

An on-line shortest path algorithm is needed to find the best policy, just as a shortest path algorithm can be used to find the best path when travel costs are fixed. A typical approach involves dynamic programming, solving a recursion of the form

$$\begin{aligned} v_s &= 0 \\ v_i &= E_\theta[\min_{(i,j) \in A} \{t_{ij} + v_j\} | \theta] \\ \pi_i(\theta) &= \arg \min_{(i,j) \in A} \{E[t_{ij} + v_j | \theta]\}, \end{aligned}$$

for an origin r and destination s where v_i represents the expected cost of the best routing policy from node i to the destination. Different assumptions on the type of information received, and on the dependence between link costs, lead to different problem scenarios and algorithms. Recently, on-line routing has been extended to traffic assignment in congested networks; the interested reader is referred to the section titled “Background” for more information.

Dynamic Traffic Assignment

Two implicit assumptions in the traffic assignment models presented above are that changes in travel demand and travel time can be ignored. On a link (i, j) , every traveler experiences the same cost $t_{ij}(x_{ij})$, based on the total demand for travel x_{ij} during the analysis period. Clearly, this is a simplification. In reality, travelers depart at different times, often in a highly nonuniform manner (for instance, shift changes at a factory). Furthermore, congestion is not static, but instead grows, shrinks, and evolves constantly based on changing demand and capacity patterns. Dynamic traffic assignment models aim to represent these changes explicitly, and thereby obtain more accurate predictions.

A considerable amount of research has been done in this field in recent years, and Peeta and Ziliaskopoulos [9] provide a comprehensive review. Broadly speaking, dynamic traffic assignment approaches can

be characterized as either analytical or simulation-based. Analytical approaches typically use exit functions or other representations of traffic flow that, while not especially sophisticated, are tractable and amenable to analysis on a large-scale. Simulation-based approaches often use a mesoscopic simulator to represent traffic flow, and seem to offer better performance on large networks, but offer less in the way of theoretical insights and properties. As the formulation of dynamic traffic assignment models diverges sharply from the network models presented in this article, the interested reader is referred to the above reference for specific details.

BACKGROUND

Traffic assignment research can be traced to Wardrop’s [10] seminal work which introduced the notion that travelers choose routes to minimize their travel time. Beckmann *et al.* [11] presented the convex programming formulation (1)–(4) and showed that the vector of link flows minimizing the objective function satisfies Wardrop’s equilibrium condition. Variational inequality formulations of the traffic assignment problem were first explored (individually) by Smith [12], Dafermos [13,14], and Marcotte [15]. Alternate representations of the traffic assignment problem not discussed in this article include nonlinear complementarity [16] and fixed-point [17] formulations.

The starting point for most commonly-used link-based solution methods is found in Frank and Wolfe’s [18] algorithm for general convex programs. Many improvements and variations of the Frank–Wolfe algorithm have been proposed for traffic assignment, as discussed in detail in by Larsson and Patricksson [19]. Route-based methods were actually proposed prior to link-based methods [20,21], but limitations in computer memory prevented their adoption for practical networks until the early 1990s. During this time, both disaggregate simplicial decomposition [19] and gradient projection [4] were found to produce solutions much more accurate than those found by link-based methods. Bush-based algorithms for user equilibrium traffic

assignment are somewhat newer. Although the concept appeared earlier in stochastic network loading [22] and roadway pricing [23] models, its usefulness for traffic assignment was independently discovered by Bar-Gera [5] and Dial [6]. More recent bush-based algorithms can be found in Nie [24] and Bar-Gera [25]. An alternate method not discussed in the article is to directly solve the variational inequality representing the equilibrium condition, as done by Marcotte [15] and Smith [26]. More details on recent variational inequality solution techniques can be found in Facchinei and Pang [27].

The concept of marginal-cost pricing leading to social optimum policy dates to Pigou [28], and early applications to adjusting user-optimal flows toward system optimality can be found in Beckmann *et al.* [11], Walters [29], Dafermos [30], and Smith [31]. Regarding network design in the traffic assignment problem, early works include LeBlanc [32], LeBlanc and Abdulaal [33,36], Dantzing *et al.* [34], and Hoang [35]. Detailed reviews of problem formulations and solution methods can be found in Magnanti and Wong [37], Boyce [38], Friesz [39], and Yang and Bell [40].

Research in stochastic user equilibrium dates to the 1970s [22,41]. The mathematical programming formulation provided in the article was developed by Sheffi and Powell [42], who built on a formulation for general discrete choice problems [43]. Representations of elastic demand can be found in Sheffi [8], Dafermos [14], and LeBlanc and Farhangian [44]. Adaptive routing problems in stochastic networks take a number of forms, depending on assumptions on link cost dependence and information structure [45–50]. Extension of adaptive routing to traffic assignment has recently been accomplished in Unnikrishnan and Waller [51]. Dynamic traffic assignment was first initiated by Merchant and Nemhauser [52,53]. Analytical models were the first to be developed, and seminal works include Carey [54,55] and Friesz *et al.* [56]. Simulation-based models grew in popularity in the late 1990s and early 2000s as computer power increased, examples of which include Jayakrishnan and Mahmassani [57], Ben-Akiva

et al. [58], Waller and Ziliaskopoulos [59], Florian *et al.* [60].

CONCLUSION

This article provided an overview of network modeling for transportation applications. The first step in developing such a model is to construct a network out of nodes and links, representing all of the features of the transportation infrastructure you wish to capture, possibly including physical infrastructure, vehicle routes, and transfer points. Next, an appropriate behavior rule must be decided for assigning travel demand onto these links. The user equilibrium rule is most commonly used, although other options are available—stochastic user equilibrium accounts for perception errors, and system optimal behavior represents the best possible network performance. Several approaches are available for solving for the link flows corresponding to the chosen behavioral rule; at present, the origin-based approaches seem to offer the best computational performance.

However, identifying link flows is only one part of the larger planning process. These link flows can then be further analyzed to obtain measures of effectiveness as part of an alternatives analysis, for instance, by using the link flows as input to an air quality model, or by using them to determine travel times between different points in the network. Equilibrium models can also be applied prescriptively, to determine congestion pricing policies or identify bottlenecks warranting improvement in a network design model.

Research in the field of transportation network analysis is extremely active, and models continue to grow more realistic in representing transportation systems, more efficient in solving large-scale problems, and more applicable to a wider variety of planning, operational, and design problems.

INTRODUCTION

Models are usually classified into two broad categories: simulation and analytic. In a *simulation model*, random variate generators or trace tapes provide time stamps of event streams (e.g., failures and end-of-repairs in a dependability model) that are processed by a computer program that mimics the system behavior. System dynamics is then observed and analyzed using statistical techniques similar to those applied to measurements. In an *analytic model*, the representation of the system is symbolic, using mathematical terms including variables, parameters, relationships such as equations and inequalities, logical statements, and data. System behavior is then studied through the solution of the derived mathematical expressions (ordinarily assisted by software tools).

Different types of analytic models can be distinguished depending on the nature of the underlying phenomena to represent, the characteristics of the system to investigate, and the solution techniques adopted in the evaluation. The models we consider in this article are based on *state space* methods due to their flexibility and power in capturing dependence conditions in the system [1–3]. The state space approach is a very general approach and can handle more cases in dependability and performance modeling than any other analytic method [4]. It can be

used when the component behaviors are *statistically independent (s-independent)* as well as for systems involving dependencies. The method proceeds by the enumeration of *system states*, that is, a collection of variables, the values of which define the state of the system at a given point in time.

State-space models may be of *deterministic* or *stochastic* nature. Stochastic models are usually the method of choice when modeling dependability since phenomena involving significant uncertainties and unpredictable variability (inherent in the system or in its inputs) frequently need to be represented. Through the probabilistic approach, the repercussions of such uncertainties in the model solution can be clearly evidenced. Stochastic models can be further classified as *Markovian* or *non-Markovian*.

The most commonly used stochastic model for performance and reliability analysis are the Markov models. A common belief, in the reliability community, is that Markov models only capture exponential distributions. This is true for the *homogeneous continuous-time Markov chain* (HCTMC), which assumes rates associated with events such as arrivals, service completions, failures, repairs, and so on are all constant in time, and the resulting sojourn times are all exponentially distributed. HCTMCs cover a wide range of real-world modeling problems. However, some behaviors of many practical systems cannot be captured by HCTMC, for example, time-dependent rates or nonexponential distributions and aging effects.

There are several interesting attempts in the literature of exploiting Markovian models such as *homogeneous* and *nonhomogeneous continuous-time Markov chains* to study systems with nonexponentially distributed behaviors. In the former case, the solution is to resort to the well-known and powerful *phase type expansion* technique that allows one to overcome the potential loss of the Markov property in dealing with nonexponential distributions. The latter alternative is to use nonhomogeneous

continuous time markov chain (NHCTMC) with time varying rates, by considering a unique and global time (no *regenerations*).

In this way, Markov models have become one of the most used paradigm in the stochastic analysis of dynamic systems in both transient and steady state, due to their modeling power and available solution techniques [3,5–7]. In this article, we deal with CTMC, and, in particular, we mainly focus on the more general NHCTMC solution techniques for their transient behavior. Thus, in the section titled “Markov Models,” we introduce the Markov modeling basics, and in the section titled “Markov Chain Analysis,” we discuss some techniques for the analysis of NHCTMC.

MARKOV MODELS

Markov models have often been used for software and hardware performance and dependability assessment. Reasons for the popularity of Markov models include the ability to capture various dependencies; the equal ease with which steady-state, transient, and cumulative transient measures can be computed; and the extension to Markov reward models, which are useful in performability analysis [8]. For example, Markov models are quite useful for systems with dependent failure and repair modes, as well as when components behave in an s-independent manner [2,5]. Furthermore, they can handle multistate devices and common-cause failures without any conceptual difficulty.

A stochastic process $\{X(t); t \in T\}$, taking values in a discrete state space Ω and indexed by a parameter set T (commonly representing the time), is called a *Markov chain* if for any $t_0 < t_1 < \dots < t_n < t$, the conditional probability mass function (pmf) of $X(t)$ for given values of $X(t_0), \dots, X(t_n)$, depends only on $X(t_n)$; that is

$$\begin{aligned} \Pr\{X(t) = x \mid X(t_n) = x_n, \dots, X(t_0) = x_0\} \\ = \Pr\{X(t) = x \mid X(t_n) = x_n\}. \end{aligned} \quad (1)$$

A Markov chain is thus a discrete state stochastic process, whose dynamic behavior is such that the probability distributions for

its future development depends only on the present state and not on how the process arrived at that state. If the conditional pmf of Equation (1), which expresses the *Markov property*, also has the property of invariance with respect to the time origin t_n ; that is

$$\begin{aligned} \Pr\{X(t) = x \mid X(t_n) = x_n\} \\ = \Pr\{X(t - t_n) = x \mid X(0) = x_n\}, \end{aligned} \quad (2)$$

the Markov chain is said to be *(time-)homogeneous*. For a homogeneous Markov chain, the past history of the process is completely summarized in the current state. Otherwise, the exact characterization of the present state needs the associated time information, and the process is said to be *nonhomogeneous*.

In the case of a *discrete-time Markov chain* (DTMC), the instants when state changes may occur are preordered to be at the integers $0, 1, 2, \dots, n, \dots \in \mathbb{N}$. In the case of a *continuous-time Markov chain* (CTMC), however, the transitions between states may take place at any instant in time.

In a homogeneous Markov chain, the Markov property imposes a heavy constraint on the distribution of time that the process may remain in a given state. In fact, the time Y_x the process spends in a given state $x \in \Omega$ is a r.v. and its distribution must be s-independent of how long it has already spent in the state. This important property, known as the *memoryless property*, is expressed as

$$\Pr\{Y_x < t + r \mid Y_x \geq t\} = \Pr\{Y_x < r\}, \quad r \geq 0. \quad (3)$$

where Y_x is a continuous random variable, and its distribution is *negative exponential*. Otherwise, the only discrete distribution with this property is the *geometric* distribution. This implies that the time that a homogeneous continuous-parameter Markov chain spends in a given state is *exponentially distributed*. Similarly, the time spent in a given state of a homogeneous discrete-parameter Markov chain is *geometrically distributed*.

Markov chains are graphically represented by state-transition diagrams, which

are directed graphs with nodes representing states and arcs representing transitions. The nodes are labeled with state names while the transitions are labeled with either transition probabilities (DTMC) or transition rates (CTMC).

As stated above, the Markov property and time-homogeneity property make the sojourn times in CTMC states exponentially distributed. This helps generating many efficient and elegant algorithms for homogeneous CTMC analysis, but it also restricts its flexibility. To make it more general, we consider CTMC without the time-homogeneity property or NHCTMC.

For NHCTMC, the following differential equation holds:

$$\frac{d\pi(t)}{dt} = \pi(t)\mathbf{Q}(t) \quad (4)$$

where $\pi(t)$ is the state probability vector at time t , $\mathbf{Q}(t) = [q_{ij}(t)]$ is the infinitesimal generator matrix, $q_{ij}(t) = \lim_{\delta \rightarrow 0} \frac{\pi_{ij}(t, t+\delta)}{\delta}$, $i \neq j$ is the transition rate from state i to state j at time t , and $q_{ii}(t) = -\sum_{j \neq i} q_{ij}(t)$, $(\pi_{ij}(t, t+h) = \Pr\{X(t+h) = x_j \mid X(t) = x_i\})$. In the case of homogeneous CTMC, $\mathbf{Q}(t)$ is time invariant and thus, $\mathbf{Q}(t) = \mathbf{Q}$.

MARKOV CHAIN ANALYSIS

There are several methods for CTMC transient analysis (both homogeneous and nonhomogeneous): the Ordinary differential equation (*ODE method*) [9–12], *piecewise approximation* [13], and *uniformization* [13–15]. But other techniques can be exploited in the solution of CTMC, applying alternative approaches (Krylov subspace, Markov renewal processes, Petri nets, fluid models, simulation, PH (phase type) expansion, metaheuristic, etc.) [16–23].

In the following, we first describe the classical CTMC solution techniques (in the sections titled “ODE Method,” “Piecewise Approximation,” and “Uniformization Method”), in particular investigating, in the section titled “Piecewise Approximation,” a specific optimized piecewise approximation algorithm. Then, in the section titled “PH

Distributions,” we discuss an NHCTMC solution technique based on PH. Other techniques are briefly reviewed in the section titled “Other Solution Techniques.”

ODE Method

For transient analysis of nonhomogeneous CTMC, we are interested in solving Equation (4), which can be seen as the following *linear initial-value problem* [24]:

$$\dot{\mathbf{y}}(t) = \mathbf{y}(t)\mathbf{Q}(t) = f(t, \mathbf{y}(t)) \quad (5)$$

In Equation (5), if $\mathbf{Q}(t)$ is piecewise continuous (or more weakly, integrable), there will exist a unique solution of the form

$$\mathbf{y}(t) = \mathbf{y}(t_0)\Phi(t, t_0) \quad (6)$$

where, in the specific case of CTMC expressed by Equation (4), letting $\pi(t) = \mathbf{y}(t)$, $\Phi(t, t_0) \in R^{m \times m}$ is the transition probability matrix mapping the initial condition $\pi(t_0)$ into $\pi(t)$, and m is the number of states of the CTMC.

If $\mathbf{Q}(t)$ and $\int_{t_0}^t \mathbf{Q}(\tau) d\tau$ commute $\forall t$, the general solution for $\Phi(t, t_0)$ can be expressed as

$$\Phi(t, t_0) = e^{\int_{t_0}^t \mathbf{Q}(\tau) d\tau} \quad (7)$$

where the matrix exponential is defined by its Taylor series expansion $e^{\int_{t_0}^t \mathbf{Q}(\tau) d\tau} \stackrel{\text{def}}{=} \sum_{i=0}^{\infty} \frac{1}{i!} \left(\int_{t_0}^t \mathbf{Q}(\tau) d\tau \right)^i$.

However, it is well known that Equation (7) is not a general solution, it is only valid under the assumption that $\mathbf{Q}(t)$ and $\int_{t_0}^t \mathbf{Q}(\tau) d\tau$ commute $\forall t$, always true in case $\mathbf{Q}(t) = \mathbf{Q}$ is time independent. A particular case in which $\mathbf{Q}(t)$ and its time integral commute is $\mathbf{Q}(t) = f(t)\mathbf{Q}$, where $f(t)$ is an arbitrary scalar function of time and $\mathbf{Q}$ is any valid time-invariant infinitesimal generator matrix. Methods for computing $\Phi(t, t_0)$ are well known for time-invariant systems, but computing it for time varying systems is more difficult.

A successful solution strategy is the discretization: we seek a solution on a discrete point set $\{t_i \mid i = 0, 1, \dots, n\}$ where $h = t_{i+1} - t_i = (b - a)/n$ is the step length (we assume h is fixed for analysis purpose but, in general, the step length may vary). Let $\mathbf{y}_i$ be

the approximation of the theoretical solution $\mathbf{y}(t_i)$ at time t_i . In computing $\mathbf{y}_{i+1}$, a method may incorporate the values from previously computed approximations $\mathbf{y}_j$ for $j = 0, 1, \dots, i$, or even $\mathbf{y}_{i+1}$ itself. A method that only uses $(t_i, \mathbf{y}_i)$ to compute $\mathbf{y}_{i+1}$ is said to be an *explicit single step method*. It is said to be a *multistep method* when it uses approximations at several previous steps to compute its new approximation. A method is said to be an *implicit method* when $\mathbf{y}_{i+1}$ requires a value for $\mathbf{y}_{i+1}$.

For a solution method, the *local truncation error* of a given step is $|\mathbf{y}_i - \mathbf{y}(t_i)|$. The *method's order* is the largest integer p such that the local truncation error is $O(h^{p+1})$. A method is *A-stable* if the numerical approximations $\mathbf{y}_n$ of $\mathbf{y}(t_n)$ approaches zero as $n \rightarrow \infty$, when applied to the differential equation $\dot{\mathbf{y}} = \lambda \mathbf{y}$ with a fixed positive h and a complex constant λ , with $\text{Re}(\lambda) < 0$. The method is *L-stable* when it is A-stable and, in addition, when applied to the equation $\dot{\mathbf{y}} = \lambda \mathbf{y}$, where λ is a complex constant with $\text{Re}(\lambda) < 0$, it yields $|\mathbf{y}_{i+1} - \mathbf{y}_i| \rightarrow 0$ as $\text{Re}(h\lambda) \rightarrow -\infty$ [25].

Most of the conventional ODE methods perform acceptably for transient analysis of nonstiff Markov models [26], that is, in case $\max\{|q_{ii}|t\}$ is not large. One of the commonly used methods is the fourth order Runge–Kutta [9,10], which is an explicit single step method, and is shown in Equation (8)

$$\mathbf{y}_{i+1} = \mathbf{y}_i + \frac{1}{6}(F_1 + 2F_2 + 2F_3 + F_4) \quad (8)$$

where

$$\begin{cases} F_1 = f(t, \mathbf{y}_i) \\ F_2 = f(t + \frac{h}{2}, \mathbf{y}_i + \frac{h}{2}F_1) \\ F_3 = f(t + \frac{h}{2}, \mathbf{y}_i + \frac{h}{2}F_2) \\ F_4 = f(t + h, \mathbf{y}_i + hF_3) \end{cases}$$

However, for stiff Markov chains explicit methods have enormous difficulty to solve the corresponding ODE. The problems stem from the fact that the solutions of stiff systems contain rapidly decaying transient terms [27]. Since explicit methods do not satisfy the A-stability property, small step sizes must be used over the entire period of integration to avoid generating large numerical errors.

Because transient solvers are often used to model a system from start-up until steady-state, explicit methods are time-consuming and often yield incorrect steady-state solution. Moreover, for extremely stiff problems, even A-stability may be inadequate. To overcome this problem, Reibman and Trivedi [11] proposed the use of TR-BDF2 method, which is an implicit two-step method with L-stability.

To compute $\mathbf{y}_{i+1}$, the TR-BDF2 method first takes a *trapezoid rule* (TR) step from t_i to $t_i + \gamma h$, where γ is a constant between 0 and 1: $0 < \gamma < 1$. The trapezoid rule applied to interval $[t_i, t_i + \gamma h]$ is

$$\mathbf{y}_{i+\gamma} - \mathbf{y}_i = \gamma h_i \cdot \frac{f(t_i, \mathbf{y}_i) + f(t_i + \gamma h_i, \mathbf{y}_{i+\gamma})}{2} \quad (9)$$

After getting $\mathbf{y}_{i+\gamma}$, we use the *second order backward differentiation formulae* (BDF2) method to step from $t_i + \gamma h$ to t_{i+1} , which is given by

$$\begin{aligned} (2 - \gamma) \mathbf{y}_{i+1} - (1 - \gamma)h_i f_{i+1} \\ = \gamma^{-1} \mathbf{y}_{i+\gamma} - \gamma^{-1}(1 - \gamma)^2 \mathbf{y}_i \end{aligned} \quad (10)$$

When computing the state probabilities with Equation (5), the TR step in Equation (9) is computationally the same as solving the first order linear algebraic system

$$\begin{aligned} \pi_{i+\gamma} [2\mathbf{I} - \gamma h_i \cdot \mathbf{Q}(t_i + \gamma h_i)] \\ = \pi_i [2\mathbf{I} + \gamma h_i \cdot \mathbf{Q}(t_i)] \end{aligned}$$

and the BDF2 step in Equation (10) becomes solving the linear system

$$\begin{aligned} \pi_{i+1} [(2 - \gamma)\mathbf{I} - (1 - \gamma)h_i \mathbf{Q}(t_i + h_i)] \\ = \gamma^{-1} \pi_{i+\gamma} - \gamma^{-1}(1 - \gamma)^2 \pi_i \end{aligned}$$

The local truncation error of TR-BDF2 method is $O(h^3)$. To better control error and provide a more efficient solution, h_i can be varied from step to step. If too much error is introduced, the step is repeated with smaller h . After a successful step, h may be increased.

Another interesting technique for dealing with stiffness in Markov chain analysis is proposed in Ref. 12 as an extension of implicit Runge–Kutta method. By exploiting the method specified in Ref. 28 and applying the Pade approximation to the resulting polynomials, the authors obtain a $2p - 1$ order method that, at each time step of constant size h , can be synthesized by the following algebraic system:

$$\pi_{i+1} \sum_{j=0}^r \alpha_j (h\mathbf{Q})^j = \pi_i \sum_{j=0}^{r-1} \beta_j (h\mathbf{Q})^j \quad (11)$$

where α_j and β_j are constants whose values are determined based upon the order $p = 2r - 1$ of the method desired. It has been shown in Ref. 29 that these methods are A-stable, and, under some specific assumptions based on the Pade approximation of polynomials, such methods are L-stable. In particular, by using $r = 2$ in Equation (11), a third order L-stable method is obtained

$$\pi_{i+1}(\mathbf{I} - 2/3h\mathbf{Q} + 1/6h^2\mathbf{Q}^2) = \pi_i(\mathbf{I} + 1/3h\mathbf{Q}). \quad (12)$$

This system can be solved by either computing the matrix polynomial directly, or by factorizing the matrix polynomial and then solving the two successive linear algebraic systems

$$\mathbf{X}(\mathbf{I} - r_2h\mathbf{Q}) = \pi_i(\mathbf{I} + 1/3h\mathbf{Q}) \quad (13)$$

$$\mathbf{X} = \pi_{i+1}(\mathbf{I} - r_1h\mathbf{Q}) \quad (14)$$

where r_1 and r_2 are the roots of the polynomial $1 - 2/3x + 1/6x^2$ corresponding to the factorization of Equation (12) into $\pi_{i+1}(\mathbf{I} - r_1h\mathbf{Q})(\mathbf{I} - r_2h\mathbf{Q}) = \pi_i(\mathbf{I} + 1/3h\mathbf{Q})$. Note that, since r_1 and r_2 are a complex conjugate pair, this requires the use of complex arithmetic.

Reference [12] provides a comprehensive overview of stiffness-tolerant methods for transient analysis of Markov chains.

Piecewise Approximation

One simple solution for the transient analysis of nonhomogeneous CTMC is the *piecewise approximation*: here a set of discrete

points $\{t_0 = 0, t_1, t_2, \dots, t_k = t\}$ is found on the continuous-time interval $[0, t]$, and the nonhomogeneous CTMC is considered to be a homogeneous CTMC in each interval $[t_i, t_{i+1}]$, $i = 0, \dots, k - 1$.

A function $f : (a, b) \subseteq \mathbb{R} \rightarrow \mathbb{R}$ is said to be *piecewise constant*, if it is locally constant in connected regions separated by a possibly infinite number of lower-dimensional boundaries. Let $t_0 = a < t_1 < \dots < t_k = b$ be such boundaries or *breakpoints*, f is constant on each interval $[t_i, t_{i+1}]$, $i = 0, 1, \dots, k - 1$. Every piecewise linear function can be written as

$$f(x) = c + \sum_{i=0}^k a_i g_i(x) = \sum_{i=0}^k f_i(x),$$

where

$$g_i(x) = \begin{cases} 1, & \text{if } t_i \leq x < t_{i+1}; \\ 0, & \text{otherwise.} \end{cases}$$

$f_i(x) = c + a_i g_i(x)$ and $a_i, c \in \mathbb{R}$ are constant values. Piecewise constant functions are often used to approximate more general functions. The piecewise constant approximation has the following three parameters that can be set in order to better fit the original function $y(x)$:

- the number of intervals k ;
- the length of each interval $[t_i, t_{i+1}]$, that can be constant or variable, depending on $i = 0, \dots, k - 1$ (adaptive according to the trend of the function to approximate);
- the value of c and a_i .

These parameters should be fixed in order to minimize the errors $e_i(x)$ and $e(x)$

$$\begin{cases} e_i(x) = y(x) - f_i(x) = y(x) - s_i, & t_i \leq x < t_{i+1}, \\ e(x) = y(x) - f(x), & a \leq x \leq b. \end{cases}$$

Each $s_i = f_i(x) \forall x \in [t_{i-1}, t_i]$, given t_i and t_{i+1} are chosen from the class of approximating functions by minimizing the norm

$$\sqrt[o]{\int_{t_{i-1}}^{t_i} |e_i(x)|^o dx},$$

where the cases $o = 1, 2, \infty$ correspond respectively to *minimum mean absolute*

deviation, least squares, and minimum maximum absolute deviation. The criterion of least squares, that is the most common and widely used in piecewise approximation problems, can be written equivalently as

$$\int_{t_i}^{t_{i+1}} e_i(x)^2 dx = \int_{t_i}^{t_{i+1}} (y(x) - s_i)^2 dx, \quad (15)$$

without taking into consideration the square root; we will use this latter form of the criterion in the following.

In the specific case, we wish to piecewise approximate the infinitesimal generator matrix $\mathbf{Q}(t) = [q_{pj}(t)]$, with $p, j = 0, \dots, m$ and $m = |\Omega|$ the number of states. In order to optimize the approximation, one way may be to separately approximate each $q_{pj}(t)$, but since each of these has its own trend, it is better to fix the number of intervals k and their common length $h = t_{i+1} - t_i$, with $i = 0, \dots, k - 1$. The only free parameter to fix is the value of $q_{pj}(t) = q_{pj}^{(i)}$ in the interval $[t_i, t_{i+1}]$, and therefore to approximate the matrix

$$\mathbf{Q}(t) = \mathbf{Q}^{(i)} = [q_{pj}^{(i)}]$$

for that interval. Given the initial probability vector $\pi(t_i)$, $\pi(t_{i+1})$ can be computed by solving the differential equation of the homogeneous CTMC:

$$\frac{d\pi(t)}{dt} = \pi(t)\mathbf{Q}^{(i)}. \quad (16)$$

For certain simple homogeneous CTMC such as the M/M/1/K queue, closed-form solution can be obtained from Equation (16) [13].

For the general case, for $t_i \leq t \leq t_{i+1}$, the solution of Equation (16) can be written as

$$\begin{aligned} \pi(t) &= \pi(t_i) \cdot \sum_{k=0}^{\infty} \frac{(\mathbf{Q}^{(i)})^k (t - t_i)^k}{k!} \\ &= \pi(t_i) \cdot e^{\mathbf{Q}^{(i)}(t - t_i)}. \end{aligned} \quad (17)$$

Given that $h = t_{i+1} - t_i$, this yields

$$\begin{aligned} \pi(t_n) &= \pi(t_{n-1}) \cdot e^{\mathbf{Q}^{(n-1)}h} = \pi(t_{n-2}) \cdot e^{\mathbf{Q}^{(n-2)}h} \\ &\cdot e^{\mathbf{Q}^{(n-1)}h} = \dots = \pi(t_0) \cdot e^{\mathbf{Q}^{(0)}h} \cdot e^{\mathbf{Q}^{(1)}h} \dots e^{\mathbf{Q}^{(n-1)}h}. \end{aligned} \quad (18)$$

Note that Equation (18) can not be simplified by summing the exponents, since $e^{\mathbf{A}}e^{\mathbf{B}} \neq e^{\mathbf{A}+\mathbf{B}}$ except when $\mathbf{A}$ and $\mathbf{B}$ commute.

Our problem is to select the best value of s_i minimizing the approximation error of Equation (15). This problem can be reformulated by considering the error as a function of two variables $e_i(x, s_i)$; taking derivative w.r.t. s_i :

$$\begin{aligned} &\frac{d}{ds_i} e_i(x, s_i) \\ &= \frac{d}{ds_i} \left(\int_{t_i}^{t_{i+1}} (y(x) - s_i)^2 dx \right) \\ &= \frac{d}{ds_i} \left(\int_{t_i}^{t_{i+1}} y^2(x) - 2s_i y(x) + s_i^2 dx \right) \\ &= 2(t_{i+1} - t_i)s_i - 2 \int_{t_i}^{t_{i+1}} y(x) dx. \end{aligned} \quad (19)$$

By setting the first derivative equal to zero

$$\begin{aligned} 2(t_{i+1} - t_i)s_i - 2 \int_{t_i}^{t_{i+1}} y(x) dx &= 0 \Rightarrow \\ s_i &= \frac{1}{t_{i+1} - t_i} \int_{t_i}^{t_{i+1}} y(x) dx, \end{aligned}$$

that is the mean value of function $y(x)$ in the interval $[t_i, t_{i+1}]$. This value is the minimum of $e_i(x, s_i)$ while varying s_i , since the second derivative of this function is positive $\frac{d^2}{ds_i^2} e_i(x, s_i) = 2(t_{i+1} - t_i) > 0$.

In order to manage pdf that have $\lambda(t_*) = \infty$ at $t_* \in [0, +\infty[\subset \mathbb{R}$ (such as the Weibull pdf with shape parameter $\alpha < 1$ or DFR in $t_* = 0$), it is necessary to consider an $0 < \epsilon \leq h$, and to evaluate the NHCTMC in the intervals $[t_* - h, t_* - \epsilon]$ and $[t_* + \epsilon, t_* + h]$.

The piecewise approximation method is simple and easy to implement using homogeneous CTMC solvers. This motivates its wider usage. However, it does not provide a rigorous error control mechanism, which makes it less preferable in real applications. In order to achieve higher accuracy, it is necessary to reduce the approximation step width h . As a consequence, the solution's execution times increase, lowering the performance of solvers and sometimes limiting the applicability of the technique.

In addition, this method is not particularly suitable for stiff Markov chains [11,12,14,27]. The ODE method and the uniformization method introduced in the following section can be used to bypass these problems.

Uniformization Method

Another way to solve the differential equation (4) is to use *uniformization* (also known as *randomization* or *Jensen's method*). This technique is based on the reduction of a CTMC with a finite state space Ω into a DTMC subordinated to a Poisson Process. Before presenting the uniformization method for nonhomogeneous CTMC, we first review it for the homogeneous case.

From a homogeneous CTMC with m states ($|\Omega| = m$) and generator matrix $\mathbf{Q} = [q_{ij}]_{m \times m}$, we obtain a DTMC $Z = \{Z_i, i = 0, 1, \dots\}$ and a Poisson process $\{N(t), t \geq 0\}$ with rate q in the following way: let $q > \max_{1 \leq i \leq m} | -q_{ii} |$, and the transition probability matrix of Z be $\mathbf{P} = \mathbf{Q}/q + \mathbf{I}$. We then form an equivalent process $\{X(t), t \geq 0\}$ as $X(t) = Z_{N(t)}$. This process is defined by the transition probability matrix $\mathbf{P}$, and the transition rate (*fictitious rate*) from each state j is equal to q , with $1 - |q_{jj}|/q$ fraction of these transitions return immediately to state j . Therefore, the probability that the process is in state j at time t is the same as that of the original CTMC.

This process is called the *uniformization* (or *randomization*) of the original CTMC, and the transient solution can be computed by conditioning on $N(t)$, the number of transitions in $[0, t]$

$$\begin{aligned} \pi_j(t) &= \Pr\{X(t) = j\} \\ &= \sum_{i=0}^{\infty} \Pr\{X(t) = j | N(t) = i\} \Pr\{N(t) = i\}. \end{aligned}$$

Thus

$$\pi(t) = \sum_{i=0}^{\infty} \mathbf{v}(i) \cdot e^{-qt} \frac{(qt)^i}{i!}, \quad (20)$$

where $\mathbf{v}(i) = \{v_1(i), v_2(i), \dots, v_m(i)\}$ is the state probability vector of the subordinated DTMC Z after i transitions, with $\mathbf{v}(0) = \pi(0)$.

Note that $\mathbf{v}(i)$ can be computed by successive matrix-vector multiplications

$$\mathbf{v}(i) = \mathbf{v}(i-1)\mathbf{P},$$

therefore Equation (20) can also be written as

$$\pi(t) = \pi(0) \sum_{i=0}^{\infty} \mathbf{P}^i \cdot e^{-qt} \frac{(qt)^i}{i!}. \quad (21)$$

To compute the solution, the uniformization series in Equation (20) needs to be truncated so as to meet the desired error tolerance. One simple error bound is based on a right-side truncation of the Poisson distribution. If the right truncation point is k , the series is truncated after the k th term. If the truncation error is bounded by ϵ , the truncated series must satisfy the following condition:

$$\epsilon \leq 1 - e^{-qt} \sum_{i=0}^k (qt)^i / i!$$

As qt grows, the Poisson pmf thins, and the terms on the left side grows slower than the former. Therefore, left truncation can also be done in order to accelerate the computation, and the left truncation error can be bounded by using a normal approximation of Poisson distribution. For dealing with stiff CTMC, Muppala and Trivedi [14] proposed the use of steady-state detection.

For nonhomogeneous CTMC with m states and generator matrix $\mathbf{Q}(t) = [q_{ij}(t)]$, assume that there exists a $q < \infty$ such that, for $\forall t < \infty, q > \max_{1 \leq i \leq m} | -q_{ii}(t) |$. We define the Poisson process $\{N(t), t \geq 0\}$ and the DTMC $Z = \{Z_i, i = 0, 1, \dots\}$ for the nonhomogeneous CTMC in the same way as for the homogeneous CTMC. The only difference is that now the transition probability matrix $\mathbf{P}$ becomes $\mathbf{P}(t)$, which is time-dependent.

Given the definitions above, the following theorem from Ref. 15 gives the uniformization series for nonhomogeneous CTMC.

Theorem 1. For all $0 \leq t \leq \infty$,

$$\begin{aligned} \pi(t) &= \pi(0) \sum_{k=0}^{\infty} \frac{(qt)^k}{k!} e^{-qt} \cdot \int_0^t \int_0^t \cdots \int_0^t \\ &\quad (t_1 \leq t_2 \leq \cdots \leq t_k) \\ &\quad \mathbf{P}(t_1) \mathbf{P}(t_2) \cdots \mathbf{P}(t_k) d\bar{H}(t_1, t_2, \dots, t_k) \\ &= \pi(0) \cdot \hat{\mathbf{U}}(t), \end{aligned} \quad (22)$$

where $d\bar{H}(t_1, t_2, \dots, t_k)$ is the density of the order statistics $t_1 \leq t_2 \leq \cdots \leq t_k$ of a k -dimensional uniform distribution at $[0, t] \times \cdots \times [0, t] \subset \mathbb{R}^k$, and $\mathbf{P}(t_1) \mathbf{P}(t_2) \cdots \mathbf{P}(t_k)$ is the standard matrix product of the transition probability matrices at times $t_1 \leq t_2 \leq \cdots \leq t_k$.

The main complication in computing the nonhomogeneous expression in Theorem 1 is the fact that a continuum of transition matrices is required. To overcome this complication, in Ref. 15 a finite-grid approximation is used. Let $0 < h < q^{-1}$ be the step-size and denote $n_i = \lfloor t_i h^{-1} \rfloor$, $i = 1, 2, \dots$, the theorem for discrete-time approximation of the uniformization series is as follows:

Theorem 2. For arbitrary n and $t = nh$, define

$$\begin{aligned} \mathbf{U}(t) = \mathbf{U}(nh) &= \sum_{k=0}^{\infty} \frac{(qt)^k}{k!} e^{-qt} \cdot \left[\sum_{\substack{n-1 \\ 0}}^{n-1} \sum_{\substack{n-1 \\ 0}}^{n-1} \cdots \sum_{\substack{n-1 \\ 0}}^{n-1} \right. \\ &\quad \left. \mathbf{P}(n_1 h) \mathbf{P}(n_2 h) \cdots \mathbf{P}(n_k h) \bar{H}(n_1, n_2, \dots, n_k), \right] \end{aligned} \quad (23)$$

where $\bar{H}$ is the pmf of the order statistics $n_1 \leq n_2 \leq \cdots \leq n_k$ of a k -dimensional uniform distribution over $\{0, 1, \dots, n-1\}^k$. With the assumption that the transition rates are Lipschitz continuous, that is,

$$\|\mathbf{Q}(t + \Delta t) - \mathbf{Q}(t)\| \leq \Delta t \cdot k,$$

it can be shown that

$$\|\mathbf{U}(t) - \hat{\mathbf{U}}(t)\| \leq ht \cdot k,$$

where $\hat{\mathbf{U}}(t)$ is the true value given in Equation (22).

Given a truncated series of $\mathbf{U}(t)$ in Theorem 2, $\pi(t)$ can be computed using $\pi(0)\mathbf{U}(t)$.

PH Distributions

Owing to its great power and flexibility, the PH approach [16] is commonly applied in the analysis of a large class of stochastic processes such as *semi-Markov process* (SMP) and *Markov regenerative process*. A possible idea is to use this technique for the solution of NHCTMC. In a generic NHCTMC, there are some transitions ($d \geq 1$) characterized by time dependent transition rates $\lambda_i(t)$, with $i = 1, \dots, d$. The concept of time in NHCTMC is *global*, in the sense that the value assumed by each timing variant failure rate at time $t = t^*$ is uniquely determined by substituting t^* in it, and so $\lambda_i(t^*)$. In other words, all $\lambda_i(t)$ evolve according to a common time t , measured from a global clock starting at the beginning of CTMC operation. By contrast, rates in an SMP are dependent on local time, measured from the time of entry into the current state.

From the PH viewpoint, it is necessary to take into account the history/memory reached by all the $\lambda_i(t)$ by means of the phases. Therefore, in general, it is necessary to substitute each state of the NHCTMC by the vector-cross product among the PH distributions representing such $\lambda_i(t)$. In this way, the transition between two states preserves the stage reached by each of the time dependent transition rates.

The main drawback of this technique is the combinatorial growth in the state space of the PH-CTMC approximation obtained. For example, consider a simple NHCTMC composed of three states (0, 1, 2) and three time dependent transitions ($0 \rightarrow 1$, $1 \rightarrow 2$, $2 \rightarrow 0$). Suppose each transition is approximated by a three phase PH. In order to take into account the phase reached by each PH, it is necessary to consider, for each of the three states, all the possible combinations among the three PH. Thus, we represent each state of the NHCTMC by a CTMC with $3 \times 3 \times 3 = 27$ nodes, and so the overall approximation of the original NHCTMC has $27 \times 3 = 81$ states.

Table 1. Summary of the Transient Behavior Analysis Techniques Discussed

Type	Name	MC	References	Equation	Algorithm	Stiff	Pros	Cons
ODE	Fourth order Runge–Kutta	*	[9,10]	(8)	Explicit single step	No	Simple, well known and widely spread.	Not adequate for stiffness.
	TR-BDF2	*	[11]	(9), (10)	Implicit two step	Yes	Easy to implement, also in case of stiffness.	It is only second-order accurate.
	($2r - 1$)th order Runge–Kutta	*	[12]	(11)–(13)	Implicit	Yes	Greater accuracy.	Complexity.
Piecewise approximation		NH	[13]	(16)–(18)	Iterative	Partial	Easy to implement.	Not adequate for stiff models.
Uniformization		*	[13,15]	(20)–(22), (1), (2)	DTMC + PP	Partial	Recommended in case of nonstiff CTMC.	Not adequate for stiff CTMC.
Stiff uniformization		*	[14]		Steady-state detection	Yes	Recommended in case of stiff CTMC.	Adequate for stiff CTMC.

PH		NH	[16]	Phase type expansion	Partial	Simple, easy to implement, general.	
Others	Krylov subspace method	H	[17]		Yes	Deal with largeness and stiffness.	Complex algorithm and parameters tuning.
	Fluid flow models	H	[18]		Yes	Powerful and general.	Some implementation could have problems with stiffnes.
	NMSPN	H	[19]		Partial	Higher level formalism large CTMC.	Problems with stiff models may arise.
	Simulation	*	[20]		Partial	Easy to implement.	Simulation has problems in dealing with stiffness Accuracy.
	Markov renewal theory	H	21		Yes	Powerful and general.	The problem is transformed into a PDE solution.
	Metaheuristic	*	[22,23]	Bayesian net	Yes	Can start from real data.	Time, due to inference procedures and logistic regression setup.

MC Type of Markov Chain.

H Homogeneous.

NH Non-Homogeneous.

*Any type both homogeneous and non-homogeneous.

Hence the PH technique is useful only for relatively simple NHCTMC, with few states and few time varying transition rates. Note that, in some cases the complexity of the overall PH-CTMC can be significantly reduced based on their specific structure.

Other Solution Techniques

Many other solution techniques exist for Markov chains, such as the Krylov subspace method [17], fluid flow [18], non-Markovian stochastic Petri nets [19], simulation [20], Markov renewal theory [21], and meta-heuristic [22]. Specific techniques have been developed in particular cases. An interesting technique for obtaining the analytical solution of periodic and aperiodic NHCTMCs based on Floquet's method is provided in Ref. 30.

Several alternatives have been developed for solving discrete-time NHMC. For example, in Ref. 22, the authors propose a hierarchical Bayesian framework for modeling and analyzing NHMC. Also, Paroli and Spezia [23] make use of Bayesian network to solve NHCTMC. Interesting results have been obtained in Ref. 31, where the problem of evaluating the steady-state of a NHMC is transformed into a more simple problem by decomposing the original NHMC into homogeneous MCs, applying the *decomposition-separation* theorem there demonstrated.

Table 1 provides a compact overview and a comparison of the techniques for evaluating the transient behavior of NHCTMC discussed in this article.

CONCLUSIONS

Markov models have become a modeling paradigm of choice in industrial and academic environments for both practical applications and theoretical research. The availability of stable and user-friendly tools based on Markov models has largely contributed to the success of this paradigm as a general purpose, flexible and effective modeling and analysis method [7,32]. The research exploiting specific properties and structures of Markov models has rapidly increased the

size of the problems that can be effectively handled. The topic has attracted much effort in the research community as evidenced by the number of papers dealing with it, and continues to offer new avenues for research.

New challenging and promising results have been recently obtained in an attempt to overcome the memoryless/exponential assumption. The possibility of dealing with nonexponential distributions represents a realistic goal with the present state of the art. In such a context, this article makes a general overview of the existing approaches, providing a detailed survey on CTMC solution techniques, with particular regard to their transient analysis.

TRANSIENT BEHAVIOR OF DTMCs

NATARAJAN GAUTAM
Department of Industrial and
Systems Engineering, Texas
A&M University, College
Station, Texas

Consider a discrete-time Markov chain (DTMC) which is a special type of stochastic process where state space is discrete and the state of the process is observed at discrete-time epochs. The observations possess the Markov property, that is, if the current state is given, to predict the future states, we do not need any information about the past. In other words, if X_n is the state of a process at the n th observation, then Markov property states that

$$\begin{aligned} P\{X_{n+1} = j | X_n = i, X_{n-1} = i_{n-1}, \\ X_{n-2} = i_{n-2}, \dots, X_0 = i_0\} \\ = P\{X_{n+1} = j | X_n = i\}. \end{aligned}$$

For the purpose of transient analysis, we also assume that the DTMC is time-homogeneous; that is, the probability of transitioning from a state to another state does not vary with time. In other words,

$$P\{X_{n+1} = j | X_n = i\} = P\{X_1 = j | X_0 = i\}.$$

This article assumes that the reader is familiar with modeling a process as a DTMC. If that is not the case, the reader is encouraged to review the previous article from this handbook or look through one of several texts on stochastic processes [1,2]. With that in mind, the objective of this article is to obtain expressions for the distribution of the states of a time-homogeneous DTMC at some particular time in the near future. Specifically, we will compute, say, $P\{X_m = j\}$, $P\{X_r = k | X_n = i\}$, and so on, for $0 \leq m < \infty$ and $n \leq r < \infty$. For that we will first describe some terminologies and notations used throughout

the article in the section titled “Terminology and Notation.” Then in the section titled “Key Results,” we present some of the key results of transient analysis. Finally, in the section titled “Computing Issues,” we provide some techniques to efficiently perform the transient analysis from a computational standpoint. For a more thorough treatment of computational aspects of DTMCs, please see the article titled ***Computational Methods for DTMCs*** in this encyclopedia.

TERMINOLOGY AND NOTATION

We consider a time-homogeneous DTMC $X_0, X_1, X_2, \dots$ which we denote as $\{X_n, n \geq 0\}$, where X_n is the state of a process at the n th observation. The state X_n could be multidimensional and when we say $X_n = i$, then i is also assumed to be multidimensional. S is the set of all possible values that X_n can take for all n . The state space S is assumed to be a countable set, although there could be infinite elements.

Next, we define p_{ij} which is the one-step transition probability of going from state i to j . Therefore, for a time-homogeneous DTMC, for $i, j \in S$ and $n \geq 0$,

$$p_{ij} = P\{X_{n+1} = j | X_n = i\}.$$

Notice that p_{ij} is not a function of n , because the DTMC is time homogeneous. Using the transition probabilities p_{ij} for every $i \in S$ and $j \in S$, we can build a square matrix $P = [p_{ij}]$. The matrix P is called *one-step transition probability matrix*. The rows of the matrix correspond to the given current state, while the columns correspond to the next state. The elements of each row sum to 1 for every $i \in S$, that is,

$$\sum_{j \in S} p_{ij} = 1.$$

An important notation for transient analysis is $p_{ij}^{(m)}$ which is the m -step transition probability of going from state i to j . In other

words, if the current state of a process is i , then the probability that exactly after m observations, the process will be in state j is $p_{ij}^{(m)}$. By definition,

$$p_{ij}^{(m)} = P\{X_{m+n} = j | X_n = i\}.$$

Note that $p_{ij}^{(1)} = p_{ij}$, the one-step transition probability. In matrix form, we denote $P(m) = [p_{ij}^{(m)}]$, the m -step transition probability matrix with $P(1) = P$. It is crucial to point out that unlike p_{ij} , which is part of the modeling, $p_{ij}^{(m)}$ can actually be computed and it forms the core of transient analysis. But before deriving an expression for $p_{ij}^{(m)}$, we present one last notation.

Let $a_j^{(m)}$ be the probability that the DTMC is in state j at the m th observation, that is,

$$a_j^{(m)} = P\{X_m = j\}.$$

The row vector of $a_j^{(m)}$ values is denoted as $\mathbf{a}^{(m)}$, that is, $\mathbf{a}^{(m)} = [a_j^{(m)}]$. To obtain $a_j^{(m)}$, we require not only P (which is described as part of the modeling) but also the initial distribution row-vector $\mathbf{a}$ which is made up of $a_j = P\{X_0 = j\}$ such that $\mathbf{a} = [a_j]$. Although $\mathbf{a}$ is not described in DTMC modeling, for the purpose of analysis (especially $\mathbf{a}^{(m)}$), we are required to know $\mathbf{a}$. Note that $\mathbf{a} = \mathbf{a}^{(0)}$. Having described the notation, the next section develops a technique to obtain $a_j^{(m)}$ and $p_{ij}^{(m)}$ for all $m < \infty$, $i \in S$, and $j \in S$.

KEY RESULTS

The results in this section for $a_j^{(m)}$ and $p_{ij}^{(m)}$ are due to the Chapman–Kolmogorov equation which we derive first. We start with the definition of $p_{ij}^{(m)}$ for $m > 0$ and some $0 < r \leq m$, and work our way:

$$\begin{aligned} p_{ij}^{(m)} &= P\{X_{m+n} = j | X_n = i\}, \\ &= \sum_{k \in S} P\{X_{m+n} = j, X_{r+n} = k | X_n = i\}, \end{aligned}$$

$$= \sum_{k \in S} P\{X_{m+n} = j | X_{r+n} = k, X_n = i\} P\{X_{r+n} = k | X_n = i\}, \quad (1)$$

$$= \sum_{k \in S} P\{X_{m+n} = j | X_{r+n} = k\} P\{X_{r+n} = k | X_n = i\}, \quad (2)$$

$$= \sum_{k \in S} P\{X_{m-r+n} = j | X_n = k\} P\{X_{r+n} = k | X_n = i\}, \quad (3)$$

$$\begin{aligned} &= \sum_{k \in S} p_{kj}^{(m-r)} p_{ik}^{(r)}, \\ &= \sum_{k \in S} p_{ik}^{(r)} p_{kj}^{(m-r)}. \end{aligned} \quad (4)$$

It may be worthwhile to explain the above set of equations. Equation (1) is just a standard conditional probability argument that follows the law of total probability statement. Then, the first term in Equation (2) is due to the Markov property and Equation (3) follows from the fact that the DTMC is time homogeneous. Finally, Equation (4) is by definition has implications in terms of the m -step transition probability matrix. Note that Equation (4) results in

$$P(m) = P(m-r)P(r)$$

since the ij th element of $P(m)$ is the left-hand side of Equation (4) and is equal to the i th row of $P(m-r)$ multiplied by the j th column of $P(r)$.

Using the result, $P(m) = P(m-r)P(r)$ for any $m > 0$ and $r \leq m$, as well as noticing that $P(0) = I$ and $P(1) = P$, we have $P(2) = P^2$ (by writing $m = 2$ and $r = 1$). Thereby, we can recursively show that

$$P(m) = P^m$$

and therefore

$$p_{ij}^{(m)} = [P^m]_{ij}.$$

Thus, starting in state i , the probability that the DTMC is in state j after m steps can be computed by raising P to the m th power and

taking the ij th term. Next, to compute $\mathbf{a}^{(m)}$ by conditioning on the initial state, we get

$$\mathbf{a}^{(m)} = aP(m) = aP^m.$$

To get $P\{X_m = j\}$, just take the term corresponding to j , that is, $[aP^m]_j$.

We illustrate the transient analysis by means of an example. Consider three long-distance telephone companies A , B , and C . Everytime a sale is announced, users switch from one company to another. Let X_n denote the long-distance company with which a particular user named Jill is just before the n th sale announcement. We have $S = \{A, B, C\}$. On the basis of the customers' switching in the past, it is estimated that Jill's switching patterns follow the following transition probability matrix:

$$P = \begin{array}{c} \begin{array}{ccc} & A & B & C \\ \begin{array}{l} A \\ B \\ C \end{array} & \begin{bmatrix} 0.3 & 0.4 & 0.3 \\ 0.5 & 0.3 & 0.2 \\ 0.4 & 0.1 & 0.5 \end{bmatrix} \end{array} \end{array}.$$

For example, if Jill is with B before a sale is announced, she would switch to A with probability 0.5 and C with probability 0.2 or stay with B with probability 0.3 as evident from the second row in P .

If at time 0, Jill is with long-distance company B , then after the third sale (i.e., $m = 3$) we wish to compute the probability that Jill is with company C . We have

$$P^3 = \begin{bmatrix} 0.3860 & 0.2770 & 0.3370 \\ 0.3930 & 0.2760 & 0.3310 \\ 0.3870 & 0.2590 & 0.3540 \end{bmatrix}.$$

What we need is

$$P\{X_3 = C | X_0 = B\} = p_{BC}^{(3)} = [P^3]_{BC} = 0.3310$$

based on the above results.

Now we know that $a = [0.25 \ 0.5 \ 0.25]$, that is, initially Jill picks A , B , or C with probability 0.25, 0.5, or 0.25, respectively. Say we are interested in computing the probability that Jill is with A after two sale announcements. On the basis of the above results, we need

$$P\{X_2 = A\} = a_A^{(2)} = [aP^2]_A = 0.385.$$

Further, using the initial distribution $a = [0.25 \ 0.5 \ 0.25]$, if we are interested in the probability that Jill is with A after the first sale, with B after the second sale, and with C after the third, then we can obtain that as

$$\begin{aligned} P\{X_1 = A, X_2 = B, X_3 = C\} \\ &= P\{X_3 = C | X_2 = B, X_1 = A\} \\ &\quad \times P\{X_2 = B | X_1 = A\}P\{X_1 = A\} \\ &= p_{BC}p_{AB}[aP]_A = 0.2 \times 0.4 \times 0.425 = 0.034 \end{aligned}$$

with the first expression being due to Markov property and the rest from the above results.

COMPUTING ISSUES

On the basis of previous section, clearly the computationally intensive operation is in obtaining P^m especially when P is large. For most problems, mathematical software such as MATLAB, mathematica, and MAPLE have efficient routines to compute P^m ; however, if one were to use a more fundamental tool such as C-programming or VBA, it would be a good idea to incorporate a routine that would efficiently obtain P^m . Having said that, in this section, we demonstrate two other techniques to obtain P^m .

Diagonalization Method

Consider a DTMC $\{X_n, n \geq 0\}$ with transition probability matrix P that is $b \times b$ square matrix, that is, the number of states in the state space S of the DTMC is b . Here, we require that b is finite. Assume that all the eigenvalues of P are distinct. Then, we can write down P as $XD X^{-1}$ where D is a diagonal matrix of all b eigenvalues of P and X is a collection of b row vectors $b \times 1$ in size that correspond to the appropriate right eigenvectors of P . We first describe a procedure to compute D and X . Let x be a right eigenvector ($b \times 1$ column vector) and d be the corresponding eigenvalue (a scalar). Then by definition of eigenvalue and eigenvector, we have $Px = dx$, that is, $(P - dI)x = 0$. Now, if we solve for the determinant $|P - dI| = 0$, we get a b -degree polynomial and upon solving we get b solutions $d_1, d_2, \dots, d_b$ which form the b eigenvalues of P . We can obtain the corresponding

eigenvectors $x_1, x_2, \dots, x_b$ by carefully solving for x_i in $Px_i = d_i x_i$ for $i = 1, 2, \dots, b$. Note that x_i is a $b \times 1$ column vector but it is not unique, so just select one arbitrarily. Once d_i and x_i are known for all $i = 1, 2, \dots, b$, we can write down

$$X = [x_1 \ x_2 \ \dots \ x_b]$$

and

$$D = \begin{bmatrix} d_1 & 0 & 0 & \dots & 0 \\ 0 & d_2 & 0 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & d_b \end{bmatrix}.$$

Therefore, we have

$$P = XDX^{-1}$$

and hence

$$P^m = XD^mX^{-1}.$$

Notice that

$$D^m = \begin{bmatrix} d_1^m & 0 & 0 & \dots & 0 \\ 0 & d_2^m & 0 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & d_b^m \end{bmatrix}.$$

The only intensive computation is in obtaining X , X^{-1} , and D . It may be worthwhile commenting on X^{-1} as there are two ways of obtaining it. One, of course, is to invert the matrix X . The other is to realize that X^{-1} is the collection of left-eigenvalues of P , stacked top to bottom corresponding to the appropriate eigenvalue.

Generating Function Method

Consider a DTMC $\{X_n, n \geq 0\}$ with transition probability matrix P that is $b \times b$ square matrix, that is, the number of states in the state space S of the DTMC is b . We can denote the generating function of P as $\Psi(z)$ for some complex scalar z . By definition,

$$\Psi(z) = I + Pz + P^2z^2 + P^3z^3 + \dots$$

and hence can be written as

$$\Psi(z) = I + Pz\Psi(z).$$

Solving for $\Psi(z)$, we get

$$\Psi(z) = (I - Pz)^{-1}$$

provided $|z| < 1$ and b is finite (although the analysis can be extended to the infinite case). From the right-hand side of the above expression, one can typically write down $[\Psi(z)]_{ij}$ of the form $\frac{f_{ij}(z)}{g_{ij}(z)}$, where both $f_{ij}(z)$ and $g_{ij}(z)$ are polynomial functions. Now, if we write down $\frac{f_{ij}(z)}{g_{ij}(z)}$ in polynomial form, it would be equivalent to $\sum_{m=0}^{\infty} p_{ij}^{(m)} z^m$ and therefore by taking the exponent multiplying z^m in $\frac{f_{ij}(z)}{g_{ij}(z)}$, we get $p_{ij}^{(m)}$.

PROBLEM OVERVIEW

The transportation problem is a classic problem in operations research. The problem has numerous applications to a wide variety of real-world situations. For example, Glover and Klingman [1] list several instances where transportation problems arise as *subproblems* in mathematical models for the production and distribution of automobiles, consumer products, textiles, lumber, agriculture as well as in applications in water management and military logistics. Although the transportation problem is not as intensively studied today as it was several decades ago, the transportation industry is still the lifeblood of the global economy and there are numerous logistics problems of modern importance where the transportation problem is an essential building block of the mathematical models used to solve these problems. These include problems such as shipping coal to power plants, crude oil to refineries, waste to recycling centers, medical supplies to hospitals, locomotives to trains, or empty shipping containers to ports. The transportation problem also arises in models other than those modeling the physical transportation of goods, including applications in designing distributed data systems [2] and large-scale circuit design [3].

This article gives an overview of the various algorithms for the transportation problem. The remainder of this section defines

the transportation problem and discusses its properties, its relationship to other problems, and its early history. The second section presents the transportation simplex method, which is the most well-known method for solving transportation problems in practice. The third section surveys other algorithms for the transportation problem. The fourth section offers concluding remarks.

Definitions and Basic Properties

Transportation Problem. The *transportation problem* asks that given a finite set of suppliers each with a finite number of units in supply, a finite set of customers each with a finite number of units in demand, and a per-unit cost of transporting between every supplier–customer pair, find a cost-minimizing transportation plan to meet all customer demands without exceeding the supply of any supplier. This problem can be expressed as a linear program. Let S be the set of suppliers and C be the set of customers. The decision variables are

$x_{ij} :=$ the number of units sent from
supplier i to customer j ,

for each $i \in S$ and $j \in C$. Let c_{ij} be the cost of sending one unit from supplier i to customer j , s_i be the number of units in supply at supplier i , and d_j be the number of units in demand at customer j . This lays the groundwork for the following linear programming formulation:

Maximize $\sum_{i \in S} \sum_{j \in C} c_{ij} x_{ij}$,

Subject to

$$\sum_{j \in C} x_{ij} \leq s_i, \quad \forall i \in S,$$

$$\sum_{i \in S} x_{ij} \geq d_j, \quad \forall j \in C,$$

$$x_{ij} \geq 0, \quad \forall i \in S, \forall j \in C.$$

Every transportation problem has an associated *transportation graph*, which is a directed graph where every supplier and

every customer has a corresponding node and there is an arc (i, j) between each supplier node i and each customer node j . In other words, the transportation graph is a directed complete bipartite graph where every arc originates at a supplier node and terminates at a customer node.

A *balanced transportation problem* is a transportation problem where $\sum_{i \in S} s_i = \sum_{j \in C} d_j$. Otherwise a transportation problem is *unbalanced*. Since any supplier can transport goods to any customer, a balanced transportation problem always has a feasible solution. A transportation problem where $\sum_{i \in S} s_i > \sum_{j \in C} d_j$ can be converted into a balanced transportation problem by adding a *dummy customer* $|C| + 1$ with demand $d_{|C|+1} = \sum_{i \in S} s_i - \sum_{j \in C} d_j$ that can absorb all of the excess demand. The cost of shipping one good from a supplier to a dummy customer is set to be equal to the cost of not shipping from that supplier. A transportation problem where $\sum_{i \in S} s_i < \sum_{j \in C} d_j$ is *infeasible* since there is not enough supply to satisfy the demands of all of the customers. Any infeasible transportation can be converted into a balanced transportation problem by adding a *dummy supplier*. The cost of shipping one good from the dummy supplier to a customer is set to be equal to the per-unit cost of not fulfilling that customer's demand.

Transshipment Problem. The *transshipment problem* is a generalization of the transportation problem that includes the possibility of *transshipment points*. Transshipment points T can receive flow from either suppliers or other transshipment points and they can send flow to either customers or other transshipment points. Transshipment points do not carry a supply nor do they have a demand, so flow balance must be maintained at every transshipment point.

The transshipment problem can be modeled with the following linear program:

$$\begin{aligned} & \text{Maximize} && \sum_{i \in S \cup T} \sum_{j \in T \cup C} c_{i,j} x_{i,j}, \\ & \text{Subject to} && \sum_{j \in T \cup C} x_{i,j} \leq s_i, \quad \forall i \in S, \end{aligned}$$

$$\begin{aligned} & \sum_{i \in S \cup T} x_{i,j} \geq d_j, \quad \forall j \in C, \\ & \sum_{i \in S \cup (T \setminus \{k\})} x_{i,k} \\ & - \sum_{j \in (T \setminus \{k\}) \cup C} x_{k,j} = 0, \quad \forall k \in T, \\ & x_{i,j} \geq 0, \quad \forall i \in S \cup T, \quad \forall j \in T \cup C. \end{aligned}$$

Input data S, C, s_i , and d_j are defined as they are in the transportation problem. The variable $x_{i,j}$ is redefined to be the number of units sent from location i to location j for each $i \in S \cup T$ and each $j \in T \cup C$ and $c_{i,j}$ is redefined similarly.

Each instance of the transshipment problem has a corresponding *transshipment graph*. There is a node for each supplier, transshipment point, and customer. In addition, there are arcs between each supplier–transshipment point pair, transshipment point–transshipment point pair, and transshipment point–customer pair.

Relationship to Other Problems. The assignment problem is a special case of the transportation problem, where $s_i = 1$ for each $i \in S$ and $d_j = 1$ for each $j \in C$. An instance of the transportation problem with integer supplies and demands can be converted into an instance of an assignment problem as follows. Replace each supplier i with s_i separate suppliers each with unit supply and replacing each customer j with d_j separate customers each with unit demand.

The minimum cost flow problem is a generalization of the transshipment problem where each arc can have both a lower bound and an upper bound on the amount of flow it can carry. In addition, the minimum cost flow problem allows arcs between any pair of nodes, whereas the transshipment problem cannot have arcs between two supply nodes or two demand nodes.

Transformations between Transportation Problem and Transshipment Problem. The transportation problem is a special case of the transshipment problem where there are no transshipment points. Moreover, a transshipment problem with nonnegative costs can be formulated as a transportation

problem. Several transformations are known [4,5]; we describe one of the transformations due to Orden [5]. Replace each transshipment point t with a new supplier u_t and a new customer v_t . Both the supply at u_t and the demand at v_t are set to $\sum_{i \in S} s_i$. The cost of sending one unit from a supplier or transshipment node i to v_t is set to $c_{i,t}$ and the cost of sending one unit from u_t to transshipment node or customer j is set to $c_{t,j}$. The cost of sending one unit from u_t to v_t is set to zero.

The intuition for how this transformation works is that each unit of flow entering a newly created customer v_t must have a corresponding unit of flow that leaves u_t . Thus, if there is a unit of flow that is sent from a supplier or transshipment node i to v_t and from u_t to a transshipment node or customer j , this is equivalent to a unit of flow being sent from i to t to j in the original transshipment problem. For any t , a unit of flow sent from u_t to v_t does not correspond to any action in the original transshipment problem and does not impact the cost of the transportation plan. Hence, setting the supply of u_t and the demand of v_t equal to $\sum_{i \in S} s_i$ is an upper bound on the amount of flow that can go through t .

Alternatively, the transshipment problem can also be reduced to the transportation problem by deleting all of the transshipment nodes and setting $c_{i,j}$ equal to the length of the shortest path from supplier i to customer j in the original transshipment graph. This reduction is polynomial if all costs are nonnegative. (This reduction is not polynomial if the costs can be negative, since the shortest path between two nodes cannot be computed in polynomial time if arc costs are negative [6].)

Properties. The constraint matrices of the transportation problem and the transshipment problem are totally unimodular. This implies, by a theorem by Hoffman and Kruskal [7], that every optimal extreme point solution to these problems is integral when the supply and demand quantities are integral. Thus, any optimal basic feasible solution to the linear programming formulation of the transportation problem or the

transshipment problem is guaranteed to have all integer values when supplies and demands are integer valued.

It is also true that a feasible solution to a balanced transportation problem is optimal if and only if there is not a *negative cost cycle* in the underlying undirected graph. In this context, a negative cost cycle is an alternating sequence of suppliers and customers:

$$s_{p(1)}, c_{q(1)}, s_{p(2)}, c_{q(2)}, \dots, s_{p(k)}, c_{q(k)}, s_{p(1)},$$

where customer $c_{q(i)}$ currently receives at least one unit from supplier $s_{p(i+1)}$, for each $i \in \{1, 2, \dots, k\}$ and $\sum_{i=1}^k c_{p(i),q(i)} < \sum_{i=1}^k c_{p(i+1),q(i)}$, where $p(k+1) = p(1)$. Such a sequence reveals how to modify the current solution to reduce its total cost. Sending one unit of supply from supplier $s_{p(i)}$ to customer $c_{q(i)}$ and sending one fewer unit of supply from supplier $s_{p(i+1)}$ to customer $c_{q(i)}$, for each $i \in \{1, 2, \dots, k\}$.

The solid arcs in Fig. 1 represent a negative cost cycle. Specifically, this cycle corresponds to the sequence: C, Y, A, X, C . To send flow around this cycle, one can send one additional unit of flow from supplier C to customer Y , send one fewer unit of flow from supplier A to customer Y , send one more unit of flow from supplier A to customer X , and send one fewer unit of flow from supplier C to customer X . Each unit of flow sent around this cycle decreases the total transportation cost by $10 - 6 + 8 - 7 = 5$ units, making it a negative cost cycle.

Both the transportation problem and the transshipment problem are strongly NP-hard if the transportation costs can be negative. This is because the strongly NP-hard shortest path problem in general networks [6] (i.e., networks where arc weights can be positive or negative) can be polynomially reduced to the transshipment problem in general networks, which in turn can be reduced to the transportation problem in general networks (see the section titled “Transformations between Transportation Problem and Transshipment Problem”). Intuitively speaking, the basic reason why the transshipment problem in general networks is NP-hard is because it is nontrivial to eliminate negative cost subtours from a solution.

Figure 1. Example of a negative cost cycle.

Early History

Schrijver [8] contains extensive notes on the early history of the transportation problems, which are summarized here. Tolstói [9] is the earliest known example of a formal study of some form of the transportation problem, which he uses to model the problem of transporting cargo over the Soviet railroad network. Kantorovich [10] and Kantorovich and Gavurin [11] also present work on precursors to the transportation problem that were motivated by logistic problems in the Soviet railroad network. However, none of these technical reports were known to Western researchers until the 1950s.

The earliest publication on the transportation problem in Western literature is by Hitchcock [12], which is why the transportation problem is often called the *Hitchcock problem*. This paper includes a linear programming formulation of the transportation problem, a simplex-like method for solving it, complementary slackness optimality conditions, and a rule for computing an initial feasible solution. The transportation problem

is also independently introduced and studied by Koopmans [13] as part of his work for a British-American merchant shipping agency during the Second World War.

TRANSPORTATION SIMPLEX METHOD

In this section, we describe a generic transportation simplex method for balanced transportation problems. Recall that any transportation problem that is not balanced can be transformed into a balanced transportation problem by the addition of a dummy supplier or customer node, as appropriate within the problem context.

Overview of Method

Algorithm 1 gives an overview of the transportation simplex method. It is essentially the same as the regular simplex method for linear programming but it exploits the special structure of the constraint matrix of the balanced transportation problem.

Demand	d_j	

Example

In this section, we present an example of a single iteration of the transportation simplex method from Winston and Venkataramanan [14]. Table 1 introduces the standard layout used in a single cell of a *transportation simplex tableau*. The value of the decision variable x_{ij} is contained in the center of the cell in the i th row and the j th column and the value of the cost coefficient c_{ij} is contained in the upper right-hand corner of that cell.

Current Basic Feasible Solution. We solve the transportation problem with data given in Table 2 starting with the current basic feasible solution listed. By convention, the values of the x_{ij} variables listed in the tableau are the basic variables and the values not listed are the nonbasic variables. Nonbasic variables are set to zero.

Checking the Reduced Costs. As with the standard simplex method, the first step of an iteration is to check the reduced costs of all of the nonbasic variables. With the standard simplex method, the reduced costs are given by the formula $c_B B^{-1} N - c_N$, where B is the basis matrix corresponding to the current basic feasible solution, N is the matrix of constraint coefficients corresponding to the nonbasic variables, c_B is the vector of objective coefficients of the basic variables, and c_N is the vector of objective coefficients of the nonbasic variables. (Our convention for

the sign of the reduced cost follows that of Winston and Venkataramanan [14]; the reduced cost is frequently defined as having the opposite sign of the quantity used here.) The reduced costs are given by the same formula for the transportation simplex method. However, due to the special structure of the constraint matrix, the reduced cost for a nonbasic variable x_{ij} simplifies to $u_i + v_j - c_{ij}$, where u_i is the dual variable associated with supplier i 's constraint and v_j is the dual variable associated with customer j 's constraint.

The reduced cost of each basic variable is zero. This fact yields the following system of equations that can be used to solve for the dual variables:

$$\begin{aligned} \bar{c}_{1,1} = u_1 + v_1 - 8 &= 0 & \bar{c}_{2,3} = u_2 + v_3 - 13 &= 0 \\ \bar{c}_{2,1} = u_2 + v_1 - 9 &= 0 & \bar{c}_{3,3} = u_3 + v_3 - 16 &= 0 \\ \bar{c}_{2,2} = u_2 + v_2 - 12 &= 0 & \bar{c}_{3,4} = u_3 + v_4 - 5 &= 0, \end{aligned}$$

where $\bar{c}_{ij}$ denotes the reduced cost of variable x_{ij} . For any transportation problem with n basic variables, there are $n + 1$ dual variables. This means the above system always consists of n equations with $n + 1$ unknown variables. Mathematically, the transportation simplex algorithm is still correct if one of the dual variables is arbitrarily set to zero. This property follows from the fact that any one of the constraints is linearly dependent upon the others, and may be deleted without affecting the set of feasible solutions. Deleting a constraint is equivalent to setting its dual variable to zero. In our example, let $u_1 = 0$. The following values for the dual variables are obtained after solving the six equations above: $u_2 = 1, u_3 = 4, v_1 = 8, v_2 = 11, v_3 = 12$, and $v_4 = 1$.

Using these dual variable values, the reduced cost of the nonbasic variables can

Table 2. Starting Basic Feasible Solution for Transportation Simplex Example

Demand	45	20	30	30	

now be computed using the following system of equations:

$$\begin{aligned}\bar{c}_{1,2} &= u_1 + v_2 - 6 = 5 & \bar{c}_{2,4} &= u_2 + v_4 - 7 = -5 \\ \bar{c}_{1,3} &= u_1 + v_3 - 10 = 2 & \bar{c}_{3,1} &= u_3 + v_1 - 14 = -2 \\ \bar{c}_{1,4} &= u_1 + v_4 - 9 = -8 & \bar{c}_{3,2} &= u_3 + v_2 - 9 = 6.\end{aligned}$$

The transportation problem is optimal if the reduced costs of all of the decision variables are nonpositive. Thus, in our example, the current basic feasible solution is not optimal.

Performing a Pivot Operation. Since the current basic feasible solution is not optimal, an *entering basic variable* must be selected. The variable with the largest (positive) reduced cost is often chosen to be the entering basic variable, which for our example is $x_{3,2}$. However, the transportation simplex method is still correct if any variable with a positive reduced cost is selected as the entering basic variable. The section titled “Choosing an Initial Basic Feasible Solution” discusses different rules for selecting an entering basic variable.

We now describe how to select a leaving basic variable. As the value of the entering variable is increased, the objective function value improves. The transportation simplex method increases the value of the entering basic variable as much as possible until a constraint is violated. During this process, the basic variables may be adjusted as required, but the other nonbasic variables must remain fixed at zero.

For instance, suppose $x_{3,2}$ is increased by Δ . This means that supplier 3 is directly

sending Δ units to customer 2, which means that supplier 3 has Δ fewer units to send to other customers. Suppose supplier 3 reduces the number of units it sends to customer 3 by Δ . (Supplier 3 cannot decrease the amount it supplies to customer 4 because there are no other suppliers that can send an additional Δ units to customer 4. Nonbasic variables $x_{1,4}$ and $x_{2,4}$ must remain fixed at 0.) Customer 3, requiring 30 units, needs to receive an extra Δ units from another supplier. Since $x_{1,3}$ must remain fixed at 0, these Δ additional units must come from supplier 2. Moreover, since supplier 2 must supply an additional Δ units to customer 3, it now has Δ fewer units to supply to other customers. However, if supplier 2 sends Δ fewer units to customer 2, then customer 2 still receives the 20 units of supply that he/she requires since he/she is now scheduled to receive $20 - \Delta$ units from supplier 2 and Δ units from supplier 3.

In summary, the solution has been modified by redefining four variables to the following values: $x_{3,2} = \Delta$, $x_{3,3} = 10 - \Delta$, $x_{2,3} = 20 + \Delta$ and $x_{2,2} = 20 - \Delta$. All other variables remain fixed to their current values. Table 3 illustrates this *transfer cycle* and the subsequent values of the decision variables as a function of Δ .

Note the supply and demand constraints remain satisfied for any value of Δ . However, the nonnegativity constraints could be violated for a sufficiently large value of Δ . In this case, Δ is set to 10 since this is the largest value Δ can assume before a basic variable assumes a negative value.

Once the basic variables are updated, $x_{3,3}$ is the basic variable that uniquely goes to zero, which makes it the only possible choice

Table 3. Finding a Transfer Cycle

	Customer 1	Customer 2	Customer 3	Customer 4	Supply

Demand	45	20	30	30	

for the *leaving basic variable*. If multiple basic variables go to zero for a given value of Δ , then one of them can be arbitrarily selected to be the leaving basic variable while the others remain in the basis with a value of 0 (these variables are said to be *degenerate*). An iteration of the transportation simplex method is concluded once a leaving basic variable is removed from the basis. Table 4 contains the new basic feasible solution that is obtained at the end of this iteration.

The transportation simplex method requires additional iterations before termination for this example because at least one of the new reduced costs is positive. The remaining iterations are omitted from this article.

When searching for a leaving basic variable, the transfer cycle created is always unique. This is because the subgraph of the transportation graph that only contains the arcs corresponding to the basic variables is a spanning tree [15]. Thus, since adding the arc to a spanning tree creates a unique cycle, the corresponding transfer cycle is also unique.

Notes on the Transportation Simplex Method

In this section, we present several additional comments on the transportation simplex method. First, we present the advantages of using the transportation simplex method over using methods designed for general linear programs. We then discuss different methods for constructing an initial basic feasible solution. We then discuss different rules for choosing an entering basic variable. Finally, we address the issue of degeneracy.

Advantages of the Transportation Simplex Method over Linear Programming Methods.

One immediately apparent advantage of the transportation simplex method over the standard simplex method for linear programming is that inverse of a basis matrix does not need to be computed and stored. Instead, the transportation simplex method requires the less costly operation of computing reduced costs by solving a simple system of equations (see the section titled “Checking the Reduced Costs”).

Computational studies have also demonstrated that the transportation simplex method is much more effective for transportation problems than the standard simplex method. For example, the landmark computational study of Glover *et al.* [16] concluded that their implementation of the transportation simplex method was over 140 times faster than the standard simplex method.

Choosing an Initial Basic Feasible Solution.

There are several methods for constructing an initial basic feasible solution to a transportation problem. One such method is the northwest corner method, which was first introduced by Dantzig [17]. This method starts in the northern-most and western-most corner of the transportation tableau (i.e., with variable $x_{1,1}$). While the method is considering variable $x_{i,j}$ it sets $x_{i,j}$ equal to the minimum of the supply remaining at supplier i and the unfulfilled demand of customer j . If $x_{i,j}$ is set equal to supplier i 's remaining supply, then the method next moves to variable $x_{i+1,j}$. Likewise, if $x_{i,j}$ is set equal to customer j 's remaining demand, then the method next moves to variable $x_{i,j+1}$. Furthermore, if supplier i 's remaining supply equals customer j 's remaining demand, then $x_{i,j}$ is set to this value. Either $x_{i+1,j}$ or $x_{i,j+1}$ is selected to be a basic variable that is set to zero. The method then proceeds to $x_{i+1,j+1}$. The method continues until all supply is exhausted and all customer demand is satisfied.

Table 5 contains an example of an initial basic feasible solution that is constructed using the northwest corner method.

This example is taken from Winston and Venkataramanan [14]. Variable $x_{1,1}$ takes the value 2 since 2 is the minimum of supplier 1's supply, which is 5, and customer 1's demand, which is 2. Since customer 1's demand is satisfied, the method next moves to variable $x_{1,2}$. Variable $x_{1,2}$ is assigned 3 since this is the minimum of the remaining supply at supplier 1, which is 3 units, and the demand of customer 2, which is 4 units. This method continues as described above until a complete basic feasible solution is constructed.

There are other methods for constructing an initial basic feasible solution. Vogel's method [18] greedily constructs a solution by iteratively selecting a supplier (or customer) with remaining supply (or demand) that has the largest difference between its smallest associated cost coefficient and its second smallest associated cost coefficient. Dennis [19] describes the row-column minimum method, which is also known as the minimum cost method Winston and Venkataramanan [14]. This method iteratively increases the decision variable with the smallest cost coefficient whose associated supplier still has unused supply and the associated customer still has unsatisfied demand. Hadley [20] describes the row minimum method that iteratively selects the decision variable with the smallest cost coefficient from a single supplier (i.e., tableau row) until the supply from that supplier is exhausted. Glover *et al.* [16] introduce a modified row minimum method that is very similar to the row minimum method but only selects one decision variable whenever a supplier is selected.

Table 5. Illustration of the Northwest Corner Method

	Customer 1	Customer 2	Customer 3	Customer 4	Supply
Supplier 1	$c_{1,1}$ 2	$c_{1,2}$ 3	$c_{1,3}$	$c_{1,4}$	5
Supplier 2	$c_{2,1}$	$c_{2,2}$ 1	$c_{2,3}$	$c_{2,4}$	1
Supplier 3	$c_{3,1}$	$c_{3,2}$ 0	$c_{3,3}$ 2	$c_{3,4}$ 1	3
Demand	2	4	2	1	

Glover *et al.* [16] test the five aforementioned methods. Their study concludes that the transportation simplex algorithm terminates with an optimal solution in the least amount of time when either the modified row minimum method or the row minimum method are employed. They also conclude that the northwest corner method is the quickest of the five rules to execute but the transportation simplex method requires roughly three times as many iterations when it starts with the northwest corner method than when it starts with the popular Vogel's method. Finally, they conclude that the transportation simplex method tends to require the fewest number of iterations when the starting solution is constructed with Vogel's method; however, the time required to construct the initial solution with Vogel's method is much larger than what is required with other methods. They also demonstrate that even though there are fewer pivots needed when Vogel's method is used, the overall time for the transportation simplex method to terminate with an optimal solution is greater when it is started with Vogel's method than when it is started with the modified row minimum method. Similar conclusions are drawn in a concurrent study by Srinivasan and Thompson [21].

In a subsequent study, Gavish *et al.* [22] suggest a modification to the modified row minimum method. Their method uses Glover's method to select the initial basic variables that assume a nonzero value. The remaining basic variables (whose values are zero) are iteratively selected by choosing the variables with the smallest cost coefficients that preserve the tree structure of the basis.

Choosing an Entering Basic Variable.

Glover *et al.* [16] also study different ways to select an entering basic variable. They conclude that the best method is to compute the reduced costs for the nonbasic variables associated with a single supplier and to only compute the reduced costs for the nonbasic variables associated with a different supplier if those associated with the previously checked supplier(s) are all nonpositive. However, when a supplier with an associated nonbasic variable with a

positive reduced cost is encountered, then the associated nonbasic variable with the most positive reduced cost should be chosen as the entering basic variable. This pivoting rule is in contrast to the standard Dantzig pivoting rule, which selects the nonbasic variable with the most positive reduced cost across *all* suppliers as the entering basic variable. Srinivasan and Thompson [21] also reach a similar conclusion about the best rule for selecting an entering basic variable in a concurrent study.

Gavish *et al.* [22] describe a complex rule for selecting an entering basic variable that involves only considering a subset of the decision variables as potential entering basic variables. The remaining variables are considered only if the current solution cannot be improved by entering any of the variables from the subset into the basis. The authors show that their pivoting rule, when combined with a few other heuristics, leads to an implementation of the transportation simplex method that outperforms the implementation of Srinivasan and Thompson [21] by an order of magnitude.

Degeneracy. Degeneracy is always a problem with simplex methods since a degenerate pivot requires the same computational costs as a regular pivot but it does not result in a solution with a better objective value. Gavish *et al.* [22] study the frequency of degenerate pivots during the transportation simplex method. They conclude that the percentage of pivots that are degenerate can be quite high, as their study found it to range from 8% for 5×5 transportation problems to 89% for 250×250 transportation problems. In addition, Gavish *et al.* show that the percentage of degenerate pivots is not sensitive to the cost coefficients but is sensitive to the range of possible levels of supply and demand. Specifically, they conclude that there is a high percentage of degenerate pivots when this range is very small.

With regards to remedies for degeneracy, Dantzig [17] describes a simple perturbation procedure that forces all basic feasible solutions to be nondegenerate. Gavish *et al.* [22] describe a simple rule for breaking ties when selecting a leaving basic variable: of all

possible leaving basic variables, choose the one with the largest cost coefficient. As previously stated, they show that their leaving basic variable tie-breaking rule, when combined with their other heuristics, yields an implementation of the transportation simplex method that outperforms the results obtained by Srinivasan and Thompson [21] by an order of magnitude.

SURVEY OF OTHER TRANSPORTATION ALGORITHMS

In this section, we offer a survey of other algorithms for the transportation problem. Research on transportation algorithms has passed through roughly three phases. The first phase consisted of researchers focusing on developing algorithms to solve transportation problems by hand. The second phase primarily consisted of researchers developing good implementations of existing algorithms to solve transportation problems on a computer. The third phase primarily consisted of researchers striving to improve the best-known worst-case algorithmic bound for a transportation problem. As the transportation problem is a special case of the minimum cost flow problem, algorithms for minimum cost flow problem can be used to solve instances of the transportation problem. Rather than present algorithms for the more general problem, we focus on specialized algorithms for the transportation problem and refer the reader to the article *Minimum Cost Flows* for a discussion of the algorithms we omit.

We partition this survey into three sections that mirror the three main phases of research on transportation problems: initial algorithmic development, computational studies, and worst-case analysis. Previous surveys on this topic include Gass [23], which surveys several computational studies of transportation algorithms. In addition, Schrijver [8] contains a survey of the best-known worst-case analysis bounds for algorithms for the transportation problem.

Initial Algorithm Development

The first transportation simplex method was engineered by Dantzig [17] and this

method is presented in the previous section. Dantzig's transportation simplex method is alternatively called the modified distribution (MODI) method as well as the row-column sum method.

Charnes and Cooper [24] subsequently developed the stepping-stone method, which is similar in essence and simpler in explanation. The key difference is that the stepping-stone method forgoes computing the values of the dual variables and the reduced costs explicitly. Instead, it considers any nonbasic variable as a potential entering basic variable, then determines the transfer cycle that results from entering that variable into the basis and then checks if sending flow along this cycle improves the objective function. Thus, the stepping-stone method could potentially compute many transfer cycles within a single iteration of the method, whereas the transportation simplex method always computes exactly one transfer cycle during each iteration.

Charnes and Cooper note that Dantzig's transportation simplex method has certain advantages during large-scale calculations. Although Charnes and Cooper do not specify these advantages, one such advantage is surely that Dantzig's method does not iteratively compute potentially large transfer cycles for many nonbasic variables until an improving entering basic variable can be identified.

Glicksman *et al.* [25] present a modified primal transportation simplex algorithm for a transportation problem with few suppliers and many customers. Their algorithm incorporates a tree structure to represent basic feasible solutions that allows them to efficiently determine a leaving basic variable. Harris [26] also develops a primal transportation simplex algorithm for problems with many customers and few suppliers. Langley *et al.* [27] create and test a primal simplex code for the related capacitated transportation problem.

There are several other algorithms that were developed throughout the 1950s and the 1960s for the transportation problem. Ford and Fulkerson [28] and Munkres [29] create new transportation algorithms by generalizing Kuhn's Hungarian method [30] for the

assignment problem. These transportation algorithms maintain a dual feasible solution and solve a restricted primal problem using only the primal variables that are nonzero in the complementary primal solution (that comes from the complementary slackness optimality conditions). Ford and Fulkerson [28] show that the restricted primal problem can be solved as a maximum flow problem.

Ford and Fulkerson [31] propose the *out-of-kilter* method for the capacitated transportation problem, where primal and dual feasible solutions are maintained and changed until conditions equivalent to complementary slackness conditions are satisfied. Graves and Thrall [32] also propose an out-of-kilter algorithm. Balinski and Gomory [33] introduce a primal version of a generalized Hungarian method for transportation problems. At each step, primal feasibility and complementary slackness are preserved, and information from the corresponding dual variables is used to avoid degenerate pivots. Grigoriadis and Walker [34] and Gass [35] propose decomposition procedures that maintain dual feasibility and strive to achieve primal feasibility. Williams [36] applies the reformulation technique of Dantzig and Wolfe [37] to a class of transportation problems and then solves the problems using a modified simplex method.

Computational Studies

After the wave of linear programming-based algorithms, the general focus of the literature shifts to determining the best implementations of transportation algorithms to solve problems on a computer in the least amount of time. These publications mostly appeared in the 1970s and they facilitated the establishment of general standards for programming languages, computational hardware, and algorithm evaluation.

During the 1960s, the out-of-kilter algorithm was considered the fastest algorithm for solving transportation problems [38, p. 109; 16, p. 796]. This perception changed after the publication of several studies in the 1970s, most notably those of Srinivasan and Thompson [21] and Glover *et al.* [16], which present primal transportation simplex

codes that found provably optimal solutions faster than the most highly regarded implementation of the out-of-kilter algorithm (i.e., Clasen's implementation [39]). Other findings of these studies are discussed in the section titled "Notes on the Transportation Simplex Method". Hatch [40] performs a subsequent study that concludes that primal-dual transportation algorithms are faster than primal transportation simplex algorithms, but the validity of the conclusions are disputed in a letter to the editor by Glover and Klingman [41] who argue that primal transportation simplex algorithms are still faster.

Bradley *et al.* [42] develop and test an implementation of the primal transportation simplex method for the capacitated transshipment problem. Their code incorporates specially designed data structures for basis representation, pivoting and computing reduced costs. Miller *et al.* [43], Barr and Hickman [44], and Li and Zenios [45] produce primal transportation algorithms designed to operate in a parallel computing environment and discuss sources of time savings from parallelization.

Worst-Case Analysis

Edmonds and Karp [46] and Dinits [47] describe the first (weakly) polynomial-time algorithm for the transportation problem. Their approach is based on solving a series of shortest path problems, which is similar in spirit to the previous approaches of Hoffman and Markowitz [48] and Lageman [49]. Edmonds and Karp employ a technique called *scaling* where only recirculations of flow that are "sufficiently large" as determined by a parameter are considered. The parameter is iteratively reduced throughout the algorithm until an optimal solution is obtained. The work of Edmonds and Karp inspired a number of other weakly polynomial scaling algorithms, including those of Gabow [50], Gabow and Tarjan [51], and Goldberg and Tarjan [52]. The first strongly polynomial algorithm for the transportation problem is presented by Tardos [53]. (Informally, an algorithm is *strongly* polynomial if the running time does not depend on the size of the numbers in the

input). Other strongly polynomial algorithms are given by Galil and Tardos [54], Goldberg and Tarjan [52], and Orlin [55].

The scaling algorithms involve either scaling of capacities, in which case a shortest path subroutine is required, or scaling of costs, in which case a maximum flow subroutine is required. The method presented by Orlin [55] is a cost-scaling method and does not require multiplication or division of numbers. Although Orlin's algorithm is designed for the more general uncapacitated minimum cost flow problem, it currently has the best worst-case algorithmic bound among known transshipment algorithms (though it does not have the best bound among transportation algorithms). Specifically, the bound is $O(n \log n \text{SP}_+(n, m, K))$, where n is the total number of nodes, m is the number of arcs, K is the largest shipping cost, and $\text{SP}_+(n, m, K)$ is the running time of an algorithm for finding a shortest path in a network with n nodes, m arcs, and with largest arc cost K .

A number of investigators propose algorithms for the transportation problem, where the number of suppliers is different from the number of customers. Bertsekas and Castanon [56] adapt an auction algorithm for the assignment problem to a transportation problem where the objective is to maximize the utility of the transportation plan. They demonstrate that their algorithm outperforms minimum cost flow codes on instances with significantly more customers than suppliers. The auction algorithm maintains dual feasibility and approximate complementary slackness conditions, while updating one or more dual variable values at each iteration. This algorithm is called an *auction algorithm* because the dual variables can be interpreted as the prices that suppliers bid to supply the customers with goods. Matsui [57] presents an algorithm for the transportation problem where the number of suppliers is small and fixed. A worst-case analysis of Matsui's algorithm shows that it runs in $O(n)$ time, where n is the number of customers but it runs in $O((m!)^2 n)$ time with m suppliers. Ahuja *et al.* [58], Tokuyama and Nakano [2], Kleinschmidt and Schannath [59], and Brenner [60] develop variants

of the scaling transportation algorithms for instances when the difference between the number of suppliers and customers is sufficiently large, and which have better worst-case algorithmic bounds than those of nonspecialized algorithms. Tokuyama and Nakano also equate the transportation problem to the geometric problem of finding a minimum-weight partitioning of points in $\mathbb{R}^k$, where k is the number of customers, and then present a randomized algorithm that improves the worst-case bound when the ratio between the minimum and maximum supply is sufficiently small.

CONCLUSIONS

Although transportation algorithms were once a popular research topic, research on problem-specific algorithms for the transportation and transshipment problems, the pace has declined in recent years. Part of this decline can probably be attributed to the similarity between the transportation, the transshipment, and the minimum cost flow problem. Also, implementations of transportation algorithms were able to solve large instances very quickly. For example, Glover *et al.* [16]'s implementation solved 1000×1000 transportation problems in a matter of seconds in the 1970s.

This is not to say that there is no opportunity for advancement in transportation algorithms. For example, Brenner *et al.* [3] details work on problems arising in chip design that can be modeled as transportation problems with millions of suppliers and several dozen customers. Such real-world instances provide motivation for examining transportation problems of much greater scale. There has been a dramatic advancement in computing power since the last major computational studies of transportation algorithms. Because of the interest in solving larger instances and because of newly available computing power, a new computational study of transportation algorithms could be of value to the research community.

In addition, Goldberg and Tarjan [52] note that the early implementations of scaling algorithms did not fare well against

traditional primal and primal–dual implementations, but they did not rule out the possibility of better implementations of scaling algorithms. Continuing to study the best implementation of scaling algorithms for transportation problems is another possible area of research.

TRANSPORTATION RESOURCE MANAGEMENT

Many problems in transportation logistics involve managing a set of resources to satisfy the service requests that arrive randomly over time. For example, truckload carriers decide which load requests they should accept and to which locations they should reposition the empty vehicles. Railroad companies deploy the empty railcars to different stations in the network to serve the random customer demand in the most effective manner. Irrespective of the application setting, transportation resource management problems pose significant challenges. To begin with, these problems tend to be large in scale, spanning transportation networks with hundreds of locations and planning horizons with hundreds of time periods. Furthermore, the service requests arrive randomly, and we may not have full information about the future service requests. When making the decisions for the current time period, we need to keep a balance between maximizing the immediate profits and getting the vehicles into favorable positions to serve the potential future service requests. Finally, the decisions that we make for different locations and for different time periods interact in a nontrivial fashion. For example, the decision to serve a particular load from location i to j at time period t affects what other loads we can serve at the future time periods, since the vehicle that is used to serve the load at time period t becomes available at location j at a future time period.

In this article, we describe a variety of modeling and algorithmic approaches

for transportation resource management problems under uncertainty. We begin with a problem that takes place over two time stages. At the first stage, we decide to which locations we should reposition the resources to serve the demands that arrive later. At the second stage, we observe the demand arrivals and decide which of these demands we should serve. The first algorithmic strategy that we discuss for the two-stage problem is based on a deterministic linear programming formulation. This formulation is simple to implement, but it does not explicitly address the randomness in the demand arrivals. Motivated by this observation, we move on to other algorithmic strategies that address the randomness in the demand arrivals by using a dynamic programming formulation. The dynamic programming formulation of the two-stage problem turns out to be computationally difficult as it involves a high dimensional state variable, and we resort to approximation strategies. In particular, the first two approximation strategies that we describe decompose the dynamic programming formulation by the locations and obtain good solutions by focusing on one location at a time. We also discuss a third approximation strategy that constructs separable value function approximations by using sampled trajectories of the system. After the discussion of two-stage problems, we move on to resource management problems that take place over multiple time periods. We give a dynamic programming formulation for a multistage resource management problem and demonstrate that the algorithmic concepts that we develop for two-stage problems can be extended to multistage problems without too much difficulty.

In addition to providing algorithmic tools for two-stage and multistage problems, we also dwell on modeling issues. Most transportation resource management problems involve complex resources. For example, a driver resource in a driver scheduling application may require keeping track of its

inbound location, time to reach the inbound location, duty time within the shift, days away from home, vehicle type, and home domicile. It would be cumbersome to model such complex entities through traditional mathematical programming tools, and we provide a flexible paradigm that is useful for modeling and communicating complex resource management problems. We conclude the article with a series of numerical experiments that demonstrate the benefits from using models that explicitly capture the randomness in the system.

Transportation resource management models have a long history dating back to the earliest days of linear programming [1–4]. The early models formulate the problem over a state time network. The nodes of the state time network represent the supply of resources at different locations and at different time periods, whereas the arcs represent the movements of the resources between different locations. These models tend to ignore the randomness in the problem and simply work with the expected values of the demand arrivals. A subclass of the deterministic models is the so-called myopic models, which ignore the unknown future altogether and only work with what is known with certainty [5–7]. This approach is justified by the fact that many customers call in advance, and a large portion of the future demands is actually known with certainty. Whether they ignore the uncertainty in the future altogether or incorporate it through expectations of the demand arrivals, these kinds of deterministic models can yield tractable optimization problems and can be relatively simple to implement. As a result, they form the backbone of many commercial systems [8–10].

The majority of the models that we discuss in this article fall under the category of stochastic models, which try to capture the random demand arrivals by formulating the problem as a dynamic program and using value functions to assess the impact of the current decisions on the future evolution of the system. The dynamic programming formulations of practical resource management problems generally involve high dimensional

state variables, and this high dimensionality makes it impossible to compute the value functions by using standard Markov decision process tools. Therefore, most of the effort is concentrated around approximating the value functions in a tractable fashion [11–20]. The overview of transportation resource management models that we give in this article is rather compact, and it mostly evolves around methods that approximate the value functions. We refer the reader to Powell *et al.* [21], Powell and Topaloglu [22], and Barnhart and Laporte [23] for detailed reviews of deterministic and stochastic models. We also emphasize that our goal in this article is to give an overview of transportation resource management models in the literature, rather than to make original contributions. At the end of each section in this article, we give pointers to the relevant literature and acknowledge the original contributors.

The article is organized as follows: In the section titled “Two-Stage Problems,” we formulate a two-stage resource management problem as a dynamic program. This formulation has a high dimensional state variable and we discuss a variety of algorithmic approaches to obtain tractable approximations. In the section titled “Multistage Problems,” we extend the ideas that we discussed in the previous section to multistage problems. In the section titled “Flexible Modelling Framework,” we give a flexible paradigm for modeling complex resource management problems. In the section titled “Numerical Illustrations,” we present numerical experiments.

TWO-STAGE PROBLEMS

In this section, we consider a resource management problem that takes place over a planning horizon of two time periods. Our goal is to illustrate the fundamental algorithmic concepts by using a relatively simple problem setting. It turns out that all of the development in this section can be extended to multistage problems without too much difficulty.

We have a set of resources that can be used over a planning horizon of two time periods

to serve the demands that arrive randomly into the system. At the beginning of the first time period, there are a certain number of resources at different locations. The decisions that we make at the first time period involve repositioning the resources between different locations so that the resources end up at favorable locations to serve the demands that arrive at the second time period. At the beginning of the second time period, we observe the demand arrivals. The decisions that we make at the second time period involve serving the demands by using the resources. The objective is to maximize the total expected profit over the two time periods, which is the difference between the total cost of repositioning the resources and the total expected revenue from serving the demands.

The set of locations in the transportation network is $\mathcal{L}$. At the beginning of the first time period, we have s_i resources available at location i , and $\{s_i : i \in \mathcal{L}\}$ is a part of the problem data. We use x_{ij} to denote the number of resources that we reposition from location i to j at the first time period. The cost of repositioning a resource from location i to j is c_{ij} . We let r_i be the number of resources available at location i at the beginning of the second time period. Naturally, $\{r_i : i \in \mathcal{L}\}$ is determined by the repositioning decisions that we make at the first time period. The set of possible demand types is $\mathcal{K}$. We use y_i^k to denote the number of demands of type k that we serve by using a resource at location i at the second time period. The revenue from serving a demand of type k by using a resource at location i is p_i^k . If it is not feasible to serve a demand of type k by using a resource at location i , then we capture this infeasibility by letting $p_i^k = -\infty$. We use the random variable D^k to represent the number of demands of type k that arrive at the second time period.

Letting $r = \{r_i : i \in \mathcal{L}\}$ and $D = \{D^k : k \in \mathcal{K}\}$ to respectively capture the number of resources at different locations and the demand arrivals at the second time period, we can determine the total revenue at the second time period by computing the value

function $V(r, D)$ through the problem

$$V(r, D) = \max \sum_{i \in \mathcal{L}} \sum_{k \in \mathcal{K}} p_i^k y_i^k \quad (1a)$$

$$\text{subject to } \sum_{k \in \mathcal{K}} y_i^k \leq r_i, \quad \forall i \in \mathcal{L}; \quad (1b)$$

$$\sum_{i \in \mathcal{L}} y_i^k \leq D^k, \quad \forall k \in \mathcal{K}; \quad (1c)$$

$$y_i^k \in \mathbb{Z}_+, \quad \forall i \in \mathcal{L}, k \in \mathcal{K}. \quad (1d)$$

In the problem above, constraint (1b) ensures that the number of resources that we use to serve the demands does not violate the resource availabilities at different locations, whereas constraint (1c) ensure that the number of demands that we serve does not exceed the demand arrivals. If the number of resources at different locations is given by the vector r , then the total expected revenue that we generate at the second time period is captured by $\bar{V}(r) = \mathbb{E}\{V(r, D)\}$. Therefore, we can maximize the total expected profit over the two time periods by solving the problem

$$Z = \max - \sum_{i \in \mathcal{L}} \sum_{j \in \mathcal{L}} c_{ij} x_{ij} + \bar{V}(r) \quad (2a)$$

$$\text{subject to } \sum_{j \in \mathcal{L}} x_{ij} = s_i, \quad \forall i \in \mathcal{L}; \quad (2b)$$

$$\sum_{i \in \mathcal{L}} x_{ij} - r_j = 0, \quad \forall j \in \mathcal{L}; \quad (2c)$$

$$x_{ij}, r_j \in \mathbb{Z}_+, \quad \forall i, j \in \mathcal{L}, \quad (2d)$$

where constraint (2b) ensures that the number of resources that we reposition does not violate the resource availabilities at different locations, and constraint (2c) computes the number of resources at different locations at the beginning of the second time period.

Conceptually, we can compute $V(r, D)$ for all possible values of the vector r and demand arrivals D by solving problem (1). In this case, we can take expectations to compute $\bar{V}(r) = \mathbb{E}\{V(r, D)\}$ for all possible values of the vector r and use this value function in problem (2) to find the optimal repositioning decisions. Practically, however, the number of possible values of the vector r and demand arrivals D can

be so large that this approach becomes computationally intractable. Therefore, we primarily focus our attention to developing methods to approximate the value function $\bar{V}(\cdot)$.

Deterministic Linear Program

A common approach for problems that take place under uncertainty is to assume that all random variables take on their expected values and to solve a deterministic approximation. In our problem setting, if we assume that all demand arrivals take on their expected values and we can utilize a fractional number of resources, then such a deterministic approximation can be written as

$$Z^{\text{DLP}} = \max - \sum_{i \in \mathcal{L}} \sum_{j \in \mathcal{L}} c_{ij} x_{ij} + \sum_{i \in \mathcal{L}} \sum_{k \in \mathcal{K}} p_i^k y_i^k \quad (3a)$$

$$\text{subject to } \sum_{j \in \mathcal{L}} x_{ij} = s_i, \quad \forall i \in \mathcal{L}; \quad (3b)$$

$$- \sum_{i \in \mathcal{L}} x_{ij} + \sum_{k \in \mathcal{K}} y_j^k \leq 0, \quad \forall j \in \mathcal{L}; \quad (3c)$$

$$\sum_{i \in \mathcal{L}} y_i^k \leq \mathbb{E}\{D^k\}, \quad \forall k \in \mathcal{K}; \quad (3d)$$

$$x_{ij}, y_j^k \in \mathbb{R}_+, \quad \forall i, j \in \mathcal{L}, k \in \mathcal{K}. \quad (3e)$$

Constraint (3b) in the problem above is analogous to constraint (2b) in the problem 2, whereas constraint (3d) is analogous to constraint (1c) in problem 1. In constraint (3d), a portion of the demands $\{D^k : k \in \mathcal{K}\}$ may be known at the beginning of the first time period, in which case, these demands simply become deterministic quantities. Constraint (3c) ensures that the number of resources that we use to serve the demands at the second time period does not violate the number of resources that we reposition at the first time period. There are two uses of the problem (3). First, this problem can be used to make resource repositioning decisions. In particular, letting $\{\hat{x}_{ij} : i, j \in \mathcal{L}\}$,

$\{\hat{y}_i^k : i \in \mathcal{L}, k \in \mathcal{K}\}$ be an optimal solution to problem 3, we can use $\{\hat{x}_{ij} : i, j \in \mathcal{L}\}$ as an approximation to the optimal solution to problem 2. The solution $\{\hat{x}_{ij} : i, j \in \mathcal{L}\}$ may utilize fractional number of resources. If this is a concern, then we can impose integrality requirements in problem (3).

The second use of problem 3 is that the optimal objective value of this problem provides an upper bound on the optimal total expected profit Z . To see the reason, we let $\{\hat{x}_{ij}(D) : i, j \in \mathcal{L}\}$, $\{\hat{y}_i^k(D) : i \in \mathcal{L}, k \in \mathcal{K}\}$ be an optimal solution and $Z^{\text{DLP}}(D)$ be the optimal objective value of problem(3) when we replace the right side of constraint(3d) with the demand arrivals $D = \{D^k : k \in \mathcal{K}\}$. In this case, $Z^{\text{DLP}}(D)$ corresponds to the perfect hindsight total profit that is computed after the demand arrivals are observed to be D . Therefore, $Z^{\text{DLP}}(D)$ is an upper bound on the total profit that is obtained by any approach when the demand arrivals are observed to be D . Taking expectations, we observe that $\mathbb{E}\{Z^{\text{DLP}}(D)\}$ is an upper bound on the total expected profit that is obtained by any approach. Since the total expected profit obtained by the optimal policy is Z , we obtain

$$Z \leq \mathbb{E}\{Z^{\text{DLP}}(D)\} \leq Z^{\text{DLP}}(\mathbb{E}\{D\}) = Z^{\text{DLP}},$$

where the second inequality follows from Jensen's inequality and the equality follows from the definition of $Z^{\text{DLP}}(\mathbb{E}\{D\})$ [24]. This kind of an upper bound on the optimal total expected profit can be useful when assessing the optimality gap of suboptimal approximation strategies, such as the ones that we develop in this article. An interesting observation from the chain of inequalities above is that $\mathbb{E}\{Z^{\text{DLP}}(D)\}$ also provides an upper bound on Z and this upper bound is tighter than the one provided by Z^{DLP} . However, to compute $\mathbb{E}\{Z^{\text{DLP}}(D)\}$, we need to compute $Z^{\text{DLP}}(D)$ for all possible values of the demand arrivals D and take an expectation. Taking this expectation can be computationally intractable when the number of possible values of the demand arrivals is large, but we can resort to Monte Carlo samples to approximate the expectation $\mathbb{E}\{Z^{\text{DLP}}(D)\}$.

Deterministic approximations similar to the one in problem 3 form the core of many practical transportation models [10]. However, such approximations may not always yield satisfactory results as they completely ignore the uncertainty in the demand arrivals. Our goal is to present models that address the uncertainty in the demand arrivals more carefully.

Separable Value Functions

In this section, we describe a special case where $\bar{V}(r) = \mathbb{E}\{V(r, D)\}$ can be computed in a tractable fashion. It turns out that we can build on the results that we obtain for this special case to develop approximation strategies for more general cases.

We consider the special case where for each demand type k , there is a single location i_k such that only the resources at location i_k can serve a demand of type k . In other words, we have $p_i^k = -\infty$ for all $i \in \mathcal{L} \setminus \{i_k\}$, which implies that $y_i^k = 0$ for all $i \in \mathcal{L} \setminus \{i_k\}$ in an optimal solution to problem 1. In this case, it is easy to see that we can replace the constraint $\sum_{i \in \mathcal{L}} y_i^k \leq D^k$ for all $k \in \mathcal{K}$ in problem 1 with the constraint $y_{i_k}^k \leq D^k$ for all $i \in \mathcal{L}$, $k \in \mathcal{K}$. If we do replace the constraint $\sum_{i \in \mathcal{L}} y_i^k \leq D^k$ for all $k \in \mathcal{K}$ in problem 1 with the constraint $y_{i_k}^k \leq D^k$ for all $i \in \mathcal{L}$, $k \in \mathcal{K}$, then all of the constraints in problem 1 decompose by the locations, and we can obtain an optimal solution to problem 1 by concentrating on one location at a time. In particular, the subproblem for location i is of the form

$$V_i(r_i, D) = \max \sum_{k \in \mathcal{K}} p_i^k y_i^k \quad (4a)$$

$$\text{subject to } \sum_{k \in \mathcal{K}} y_i^k \leq r_i, \quad (4b)$$

$$y_i^k \leq D^k, \quad \forall k \in \mathcal{K}; \quad (4c)$$

$$y_i^k \in \mathbb{Z}_+, \quad \forall k \in \mathcal{K}, \quad (4d)$$

and we have $V(r, D) = \sum_{i \in \mathcal{L}} V_i(r_i, D)$. An important observation is that problem 4 is a knapsack problem. The capacity of the knapsack is r_i . There are $|\mathcal{K}|$ items, each item occupies one unit of space, and we can put at most D^k units of item k into the knapsack.

Therefore, it is possible to solve problem 4 by sorting the objective function coefficients of the items and putting the items into the knapsack starting from the item with the largest objective function coefficient.

We need the value function $\bar{V}(r) = \sum_{i \in \mathcal{L}} \mathbb{E}\{V_i(r_i, D)\}$ to compute the optimal repositioning decisions through problem 2. It turns out that taking this expectation is tractable due to the knapsack structure of problem 4. We assume, without loss of generality, that the set of demand types is $\mathcal{K} = \{1, 2, \dots, K\}$ and the demand types are ordered such that $p_i^1 \geq p_i^2 \geq \dots \geq p_i^K$. Noting the knapsack interpretation of problem 4, we let $\psi_i^k(q)$ be the probability that the k th item uses the q th unit of available space in the knapsack for location i . In this case, the expected revenue that we generate from the q th unit of available space becomes $\sum_{k \in \mathcal{K}} \psi_i^k(q) p_i^k$ and the expectation of the optimal objective value of problem 4 can be computed as

$$\mathbb{E}\{V_i(r_i, D)\} = \sum_{q=1}^{r_i} \sum_{k \in \mathcal{K}} \psi_i^k(q) p_i^k.$$

To compute $\psi_i^k(q)$, we observe that for the k th item to use the q th unit of available space in the knapsack, the total amount of space used by the first $k-1$ items should be strictly smaller than q , the total amount of space used by the first k items should be greater than or equal to q , and item k should satisfy $i_k = i$, since otherwise we have $p_i^k = -\infty$ and it is never desirable to put the k th item into the knapsack. Therefore, we have $\psi_i^k(q) = \mathbb{P}\{D^1 + \dots + D^{k-1} < q \leq D^1 + \dots + D^k\}$ if $i_k = i$, and $\psi_i^k(q) = 0$ otherwise. This implies that we can compute $\psi_i^k(q)$ in a tractable fashion as long as we can compute the convolutions of the distributions of $\{D^k : k \in \mathcal{K}\}$, which is the case when the demand random variables have, for example, independent Poisson distributions.

The approach outlined above is proposed by Cheung [25]. Powell and Cheung [26], Powell and Cheung [27], Cheung and Powell [28], and Cheung and Powell [29] apply this approach to a variety of settings, including dynamic fleet management and inventory

distribution. An interesting aspect of this approach is that it not only allows us to compute $\bar{V}(r) = \mathbb{E}\{V(r, D)\}$ in a special case, but also allows us to construct approximations when the special case does not necessarily hold. This is the topic of the next section.

Decomposition by Demand Relaxation

In this section, we demonstrate how we can build on the special case that we discuss in the section titled “Separable Value Functions” to construct tractable approximation strategies for more general cases. The fundamental idea is to relax the constraint (1c) in the problem 1 by associating the nonnegative Lagrange multipliers $\lambda = \{\lambda^k : k \in \mathcal{K}\}$ with it. In this case, the relaxed version of problem 1 becomes

$$V^{\text{DDR}}(r, D, \lambda) = \max \sum_{i \in \mathcal{L}} \sum_{k \in \mathcal{K}} [p_i^k - \lambda^k] y_i^k + \sum_{k \in \mathcal{K}} \lambda^k D^k \quad (5a)$$

$$\text{subject to } \sum_{k \in \mathcal{K}} y_i^k \leq r_i, \quad \forall i \in \mathcal{L}; \quad (5b)$$

$$y_i^k \leq D^k, \quad \forall i \in \mathcal{L}, k \in \mathcal{K}; \quad (5c)$$

$$y_i^k \in \mathbb{Z}_+, \quad \forall i \in \mathcal{L}, k \in \mathcal{K}. \quad (5d)$$

The constraint (5c) would be redundant in problem 1, but we add it to the problem above to tighten the relaxation. We use the argument λ in the value function $V^{\text{DDR}}(r, D, \lambda)$ to emphasize that the optimal objective value of problem 5 depends on the Lagrange multipliers that we associate with the constraint $\sum_{i \in \mathcal{L}} y_i^k \leq D^k$ for all $k \in \mathcal{K}$. The superscript *DDR* in the value function stands for decomposition by demand relaxation.

Noting that all of the constraints in problem 5 decompose by the locations, we can obtain an optimal solution to this problem by concentrating on one location at a time. In this case, the subproblem for location i has the same form as problem 4 with the exception that the objective

function of the subproblem for location i now reads $\sum_{k \in \mathcal{K}} [p_i^k - \lambda^k] y_i^k$ instead of $\sum_{k \in \mathcal{K}} p_i^k y_i^k$. This implies that we can compute $\mathbb{E}\{V^{\text{DDR}}(r, D, \lambda)\}$ in a tractable fashion by using the approach that we describe in the previous section. Furthermore, it is possible to show that the demand relaxation strategy provides an upper bound on the optimal total expected profit. To see the reason, we let $\{\hat{y}_i^k : i \in \mathcal{L}, k \in \mathcal{K}\}$ be an optimal solution to problem 1 and note that

$$V(r, D) = \sum_{i \in \mathcal{L}} \sum_{k \in \mathcal{K}} p_i^k \hat{y}_i^k \leq \sum_{i \in \mathcal{L}} \sum_{k \in \mathcal{K}} [p_i^k - \lambda^k] \hat{y}_i^k + \sum_{k \in \mathcal{K}} \lambda^k D^k \leq V^{\text{DDR}}(r, D, \lambda). \quad (6)$$

The first inequality follows from the fact the Lagrange multipliers are nonnegative and we have $\sum_{i \in \mathcal{L}} \hat{y}_i^k \leq D^k$ for all $k \in \mathcal{K}$ by constraint (1c) in the problem 1. The second inequality follows from the fact that $\{\hat{y}_i^k : i \in \mathcal{L}, k \in \mathcal{K}\}$ is a feasible, but not necessarily an optimal, solution to problem 5. Taking expectations, we obtain $\bar{V}(r) = \mathbb{E}\{V(r, D)\} \leq \mathbb{E}\{V^{\text{DDR}}(r, D, \lambda)\}$. Therefore, if we replace $\bar{V}(r)$ in the objective function of problem 2 with $\mathbb{E}\{V^{\text{DDR}}(r, D, \lambda)\}$ and solve this problem, then the resulting objective function value $Z^{\text{DDR}}(\lambda)$ provides an upper bound on the optimal total expected profit Z , as long as the Lagrange multipliers are nonnegative.

There are several approaches that we can use to choose a good set of Lagrange multipliers. To begin with, we note that $Z^{\text{DDR}}(\lambda) \geq Z$ whenever we have $\lambda \geq 0$. Therefore, we can solve the problem $\min_{\lambda \geq 0} Z^{\text{DDR}}(\lambda)$ to obtain the tightest possible upper bound on the optimal total expected profit and use the optimal solution to this problem as the Lagrange multipliers. Cheung and Powell [29] show that $Z^{\text{DDR}}(\lambda)$ is a convex function of λ so that the problem $\min_{\lambda \geq 0} Z^{\text{DDR}}(\lambda)$ can be solved by using standard subgradient optimization. A possible shortcoming of this approach is that solving the problem $\min_{\lambda \geq 0} Z^{\text{DDR}}(\lambda)$ can be time consuming. Kunnumkal and Topaloglu [30] propose another approach for choosing the Lagrange multipliers that uses the dual solution to problem 3. In particular, they note that constraint (3d) in problem 3 is analogous to constraint (1c) in problem 1. In this case, letting $\hat{\lambda} = \{\hat{\lambda}^k : k \in \mathcal{K}\}$ be the optimal

values of the dual variables associated with constraint(3d) in problem 3, they choose the Lagrange multipliers as $\hat{\lambda}$. Since $\hat{\lambda} \geq 0$ by dual feasibility to problem 3, we have $Z^{\text{DDR}}(\hat{\lambda}) \geq Z$. Furthermore, Kunnumkal and Topaloglu [30] show that $Z^{\text{DDR}}(\hat{\lambda}) \leq Z^{\text{DLP}}$, and we obtain

$$Z \leq \min_{\lambda \geq 0} Z^{\text{DDR}}(\lambda) \leq Z^{\text{DDR}}(\hat{\lambda}) \leq Z^{\text{DLP}}.$$

Therefore, the demand relaxation strategy provides an upper bound on the optimal total expected profit, and this upper bound is tighter than the one provided by the deterministic approximation.

The demand relaxation strategy is proposed by Cheung [25], but the idea of relaxing complicating constraints in stochastic optimization problems frequently appears in the literature. Ruszczyński [31] gives an overview of this idea within the framework of general stochastic programs. Adelman and Mersereau [32] introduce the term “weakly coupled dynamic program” to refer to a stochastic optimization problem which would decompose if a few linking constraints did not exist. They study a dual framework for such stochastic optimization problems. Cheung and Powell [28,29] provide applications of the demand relaxation strategy to dynamic fleet management and inventory distribution problems. Similar relaxation ideas are used by Castanon [33], Yost and Washburn [34], and Bertsimas and Mersereau [35] in partially observable Markov decision processes, by Federgruen and Zipkin [36], Topaloglu and Kunnumkal [37], and Kunnumkal and Topaloglu [38] in inventory distribution, and by Erdelyi and Topaloglu [39], Kunnumkal and Topaloglu [40], and Topaloglu [41] in airline network revenue management.

Decomposition by Supply Relaxation

In this section, we construct a tractable approximation strategy by using a relaxation idea that is conceptually similar to the one in the previous section, but the specific details of this relaxation idea are quite different. We begin by choosing an arbitrary location i and relax constraint (1b) in problem 1 for all other

locations by associating the nonnegative Lagrange multipliers $\mu = \{\mu_j : j \in \mathcal{L} \setminus \{i\}\}$ with them. In this case, the relaxed version of problem 1 becomes

$$V_i^{\text{DSR}}(r, D, \mu) = \max \sum_{k \in \mathcal{K}} p_i^k y_i^k + \sum_{j \in \mathcal{L} \setminus \{i\}} \sum_{k \in \mathcal{K}} [p_j^k - \mu_j] y_j^k + \sum_{j \in \mathcal{L} \setminus \{i\}} \mu_j r_j \quad (7a)$$

$$\text{subject to } \sum_{k \in \mathcal{K}} y_i^k \leq r_i, \quad (7b)$$

$$y_i^k + \sum_{j \in \mathcal{L} \setminus \{i\}} y_j^k \leq D^k, \forall k \in \mathcal{K}; \quad (7c)$$

$$y_i^k, y_j^k \in \mathbb{Z}_+, \forall j \in \mathcal{L} \setminus \{i\}, k \in \mathcal{K}. \quad (7d)$$

The subscript i in the value function $V_i^{\text{DSR}}(r, D, \mu)$ emphasizes that the optimal objective value of the problem above depends on the choice of location i , and the superscript *DSR* stands for decomposition by supply relaxation.

It is possible to show that problem 7 has the same structure as problem 4, in which case, we can compute $\mathbb{E}\{V_i^{\text{DSR}}(r, D, \mu)\}$ by using the approach that we describe in the section titled “Separable Value Functions.” To see the equivalence between problems 4 and 7, we first observe that the decision variables $\{y_j^k : j \in \mathcal{L} \setminus \{i\}, k \in \mathcal{K}\}$ appear only in constraint (7c) in problem 7. This implies that we can replace the decision variables $\{y_j^k : j \in \mathcal{L} \setminus \{i\}\}$ with a single decision variable, and the objective function coefficient of this decision variable would be $\max_{j \in \mathcal{L} \setminus \{i\}} [p_j^k - \mu_j]$. Therefore, letting $\rho^k = \max_{j \in \mathcal{L} \setminus \{i\}} [p_j^k - \mu_j]$ for notational brevity and replacing the decision variables $\{y_j^k : j \in \mathcal{L} \setminus \{i\}\}$ with the single decision variable z^k , problem 7 can be written as

$$\max \sum_{k \in \mathcal{K}} p_i^k y_i^k + \sum_{k \in \mathcal{K}} \rho^k z^k + \sum_{j \in \mathcal{L} \setminus \{i\}} \mu_j r_j \quad (8a)$$

$$\text{subject to } \sum_{k \in \mathcal{K}} y_i^k \leq r_i, \quad (8b)$$

$$y_i^k + z^k \leq D^k, \forall k \in \mathcal{K}; \quad (8c)$$

$$y_i^k, z^k \in \mathbb{Z}_+, \forall k \in \mathcal{K}. \quad (8d)$$

We assume without loss of generality that $\rho^k \geq 0$ for all $k \in \mathcal{K}$. If there exists some $k \in \mathcal{K}$ such that $\rho^k < 0$, then the corresponding decision variable z^k takes value zero in an optimal solution, and this decision variable can be dropped from problem 8 without changing the optimal objective value. Since we have $\rho^k \geq 0$ for all $k \in \mathcal{K}$, the decision variables $\{z^k : k \in \mathcal{K}\}$ take their largest possible values in an optimal solution and the largest possible values of these decision variables are $\{D^k - y_i^k : k \in \mathcal{K}\}$. Therefore, we can replace the decision variables $\{z^k : k \in \mathcal{K}\}$ in the problem above with $\{D^k - y_i^k : k \in \mathcal{K}\}$ and obtain the equivalent problem

$$\begin{aligned} \max \quad & \sum_{k \in \mathcal{K}} [p_i^k - \rho^k] y_i^k + \sum_{k \in \mathcal{K}} \rho^k D^k \\ & + \sum_{j \in \mathcal{L} \setminus \{i\}} \mu_j r_j \end{aligned} \quad (9a)$$

$$\text{subject to } \sum_{k \in \mathcal{K}} y_i^k \leq r_i, \quad (9b)$$

$$y_i^k \leq D^k, \forall k \in \mathcal{K}; \quad (9c)$$

$$y_i^k \in \mathbb{Z}_+, \forall k \in \mathcal{K}. \quad (9d)$$

Ignoring the constant terms $\sum_{k \in \mathcal{K}} \rho^k D^k$ and $\sum_{j \in \mathcal{L} \setminus \{i\}} \mu_j r_j$, problem 9 has the same structure as problem 4. By using an argument similar to the one in 6, we can show that $V(r, D) \leq V_i^{\text{DSR}}(r, D, \mu)$ as long as the Lagrange multipliers are nonnegative [42].

Since the choice of location i is arbitrary, we have $V(r, D) \leq V_i^{\text{DSR}}(r, D, \mu)$ for all $i \in \mathcal{L}$, and it is not clear which one of $\{V_i^{\text{DSR}}(r, D, \mu) : i \in \mathcal{L}\}$ we should use as an approximation to $V(r, D)$. We resolve this ambiguity by averaging over all $i \in \mathcal{L}$ and using $\frac{1}{|\mathcal{L}|} \sum_{i \in \mathcal{L}} V_i^{\text{DSR}}(r, D, \mu)$ as an approximation to $V(r, D)$. Noting that $V_i^{\text{DSR}}(r, D, \mu)$ is an upper bound on $V(r, D)$ for all $i \in \mathcal{L}$, $\frac{1}{|\mathcal{L}|} \sum_{i \in \mathcal{L}} V_i^{\text{DSR}}(r, D, \mu)$ is also an upper bound on $V(r, D)$. In this case, if we replace $\bar{V}(r)$ in the objective function of problem 2 with $\frac{1}{|\mathcal{L}|} \sum_{i \in \mathcal{L}} \mathbb{E}\{V_i^{\text{DSR}}(r, D, \mu)\}$ and solve this problem, then the resulting objective function value $Z^{\text{DSR}}(\mu)$ provides an upper bound on the optimal total expected profit Z , as long as we have $\mu \geq 0$.

The methods that we use to choose a good set of Lagrange multipliers are similar to those in the section titled “Decomposition by Demand Relaxation.” In particular, we can solve the problem $\min_{\mu \geq 0} Z^{\text{DSR}}(\mu)$ to obtain the tightest possible upper bound on Z and use the optimal solution to this problem as the Lagrange multipliers. It is possible to show that $Z^{\text{DSR}}(\mu)$ is a convex function of μ so that we can solve the problem $\min_{\mu \geq 0} Z^{\text{DSR}}(\mu)$ by using standard subgradient optimization. Another approach for choosing a good set of Lagrange multipliers is based on the dual solution of problem 3. We note that constraint (1b) in problem 1 captures the resource availabilities at different locations at the beginning of the second time period. Similarly, constraint (3c) in problem 3 captures the resource availabilities at different locations. Therefore, letting $\{\hat{\mu}_i : i \in \mathcal{L}\}$ be the optimal values of the dual variables associated with constraint (3c) in problem 3, we can choose the Lagrange multipliers as $\{\hat{\mu}_j : j \in \mathcal{L} \setminus \{i\}\}$.

The supply relaxation strategy has its roots in the network revenue management literature. In this literature, it is customary to relax the capacity constraints for all of the flight legs except for one and to obtain approximations to the value function by concentrating on one flight leg at a time [43]. Zhang and Adelman [42] establish that the supply relaxation strategy provides an upper bound on the value function. Kunnumkal and Topaloglu [44, 45] provide alternative proofs for the same result. Erdelyi and Topaloglu [46] use the supply relaxation idea to solve an overbooking problem. Topaloglu [47] extends the supply relaxation strategy to general stochastic programs and provides applications in dynamic fleet management.

Separable Projective Approximations

In this section, we describe an iterative approach that uses sampled realizations of the demand arrivals to construct a separable approximation to the value function. The fundamental idea is to approximate the value function $\bar{V}(r)$ with a separable function of the form

$$V^{\text{SPA}}(r) = \sum_{i \in \mathcal{L}} V_i^{\text{SPA}}(r_i),$$

where the approximations $\{V_i^{SPA}(\cdot) : i \in \mathcal{L}\}$ are single dimensional, piecewise linear and concave functions with points of nondifferentiability being a subset of integers. The superscript SPA stands for separable projective approximations. The concavity of the approximation $V_i^{SPA}(\cdot)$ is intended to capture the intuitive expectation that the marginal benefit from an additional resource at a location should be decreasing as we have more resources available at the location. Noting that $V_i^{SPA}(\cdot)$ is a piecewise linear function with points of nondifferentiability being a subset of integers, if we have a total of Q available resources, then we can characterize the approximation $V_i^{SPA}(\cdot)$ with a sequence of Q slopes $\{v_i(q) : q = 0, \dots, Q-1\}$, where $v_i(q)$ is the slope of $V_i^{SPA}(\cdot)$ over the interval $[q, q+1]$. In other words, we have $v_i(q) = V_i^{SPA}(q+1) - V_i^{SPA}(q)$.

We use an iterative approach to construct the approximations $\{V_i^{SPA}(\cdot) : i \in \mathcal{L}\}$. In particular, letting $\{V_i^{SPA,n}(\cdot) : i \in \mathcal{L}\}$ be the approximations at iteration n , we begin by solving problem 2 after replacing $\bar{V}(r)$ in the objective function with $\sum_{i \in \mathcal{L}} V_i^{SPA,n}(r_i)$. This provides an optimal solution $\{\hat{x}_{ij}^n : i, j \in \mathcal{L}\}$, $\{\hat{r}_i^n : i \in \mathcal{L}\}$. We then sample a realization of the demand arrivals, which we denote by $\{\hat{D}^{k,n} : k \in \mathcal{K}\}$. We solve problem 1 after replacing the right side of constraint (1b)

with $\hat{r}^n = \{\hat{r}_i^n : i \in \mathcal{L}\}$ and the right side of constraint (1c) with $\hat{D}^n = \{\hat{D}^{k,n} : k \in \mathcal{K}\}$. The challenge is to use the solution to problem 1 to improve the approximations $\{V_i^{SPA,n}(\cdot) : i \in \mathcal{L}\}$. We give a description of the general approach in Fig. 1. In Step 1, we initialize the approximations $\{V_i^{SPA,n}(\cdot) : i \in \mathcal{L}\}$ to arbitrary piecewise linear and concave functions with points of nondifferentiability being a subset of integers. In Step 2, we solve problem 2 after replacing $\bar{V}(r)$ in the objective function with the value function approximation $\sum_{i \in \mathcal{L}} V_i^{SPA,n}(r_i)$. In Step 3, we sample a realization of the demand arrivals and solve problem 1 by using the sampled demand arrivals and the resource availabilities obtained from problem 2. In Step 4, we update the approximations $\{V_i^{SPA,n}(\cdot) : i \in \mathcal{L}\}$, and this provides the approximations $\{V_i^{SPA,n+1}(\cdot) : i \in \mathcal{L}\}$ that we use at the next iteration.

The approach that we use to update the approximations is based on a stochastic approximation idea, but we need to be careful to preserve the concavity of the value function approximation. Using e_i to denote the $|\mathcal{L}|$ dimensional unit vector with a one in the element corresponding to $i \in \mathcal{L}$, we let $\hat{\vartheta}_i^n = V(\hat{r}^n + e_i, \hat{D}^n) - V(\hat{r}^n, \hat{D}^n)$. Therefore, $\hat{\vartheta}_i^n$ captures the marginal benefit from an additional resource at location i in problem 1 when the number of resources at different

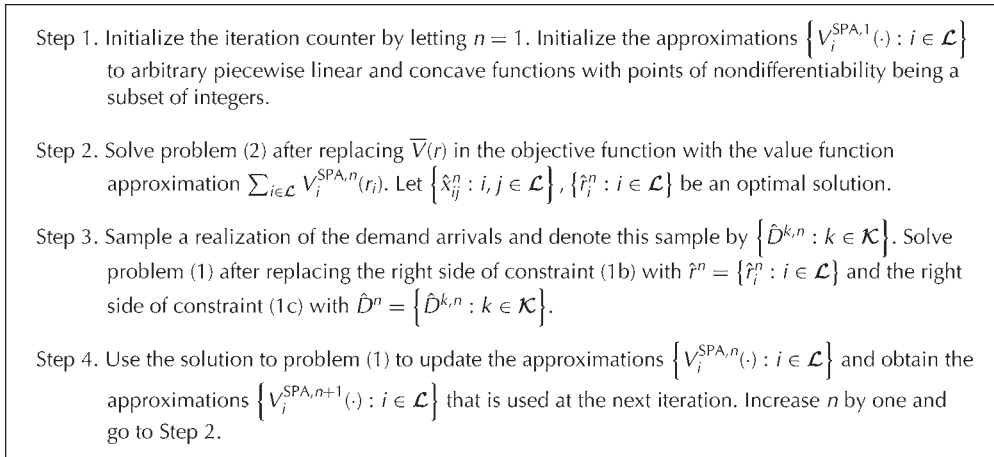

Figure 1. An iterative approach to construct a separable value function approximation.

locations is given by $\hat{r}^n = \{\hat{r}_i^n : i \in \mathcal{L}\}$ and the realization of the demand arrivals is given by $\hat{D}^n = \{\hat{D}^{k,n} : k \in \mathcal{K}\}$. In this case, letting $V_i^{SPA,n}(\cdot)$ be the piecewise linear and concave function characterized by the sequence of slopes $\{v_i^n(q) : q = 0, \dots, Q-1\}$, we update these slopes as

$$\gamma_i^n(q) = \begin{cases} [1 - \alpha^n] v_i^n(q) + \alpha^n \hat{v}_i^n & \text{if } q = \hat{r}_i^n \\ v_i^n(q) & \text{otherwise,} \end{cases}$$

where $\alpha^n \in [0, 1]$ is the step size parameter at iteration n . Since we may not have $\gamma_i^n(0) \geq \gamma_i^n(1) \geq \dots \geq \gamma_i^n(Q-1)$, the piecewise linear function characterized by the sequence of slopes $\{\gamma_i^n(q) : q = 0, \dots, Q-1\}$ is not necessarily concave. To obtain a concave approximation, we solve the problem

$$\min \sum_{q=0}^{Q-1} [w(q) - \gamma_i^n(q)]^2$$

subject to $w(q) \geq w(q+1)$, $\forall q = 0, \dots, Q-2$.

Letting $\{\hat{w}(q) : q = 0, \dots, Q-1\}$ be an optimal solution to the problem above, we use the sequence of slopes $\{\hat{w}(q) : q = 0, \dots, Q-1\}$ to characterize the approximation $V_i^{SPA,n+1}(\cdot)$. Since we have $\hat{w}(0) \geq \hat{w}(1) \geq \dots \geq \hat{w}(Q-1)$, the approximation $V_i^{SPA,n+1}(\cdot)$ is indeed concave. Intuitively speaking, the quadratic program above projects the piecewise linear function characterized by the sequence of slopes $\{\gamma_i^n(q) : q = 0, \dots, Q-1\}$ onto the set of piecewise linear and concave functions with points of nondifferentiability being a subset of integers. Throughout this article, we use $V_i^{SPA,n+1}(\cdot) = \mathcal{U}(V_i^{SPA,n}(\cdot), \hat{r}_i^n, \hat{v}_i^n, \alpha^n)$ to succinctly capture the updating procedure.

The separable projective approximations are proposed by Powell *et al.* [48]. The authors develop several convergence results for the updating procedure that we describe above, and these convergence results have close connections with the stochastic approximation theory. Topaloglu and Powell [18] and Topaloglu [49] use the separable projective approximations for dynamic fleet management problems. Godfrey and Powell [50] use

separable approximations to the value functions in a product distribution problem, but the method they use to update the approximations is different from the one that we describe above. Godfrey and Powell [14,15] apply the approach in Ref. 50 to dynamic fleet management problems. Cheung and Powell [51] and Topaloglu and Powell [52] propose alternative methods to construct separable and concave value function approximations. Both of these methods are rooted in the stochastic approximation theory as well. Cheung and Chen [53] apply the method that is developed in Ref. 51 to an empty container allocation problem. Stochastic approximation methods date back to Robbins and Monro [54]. Kushner and Clark [55], Benveniste *et al.* [56], Bertsekas and Tsitsiklis [57], and Kushner and Yin [58] provide detailed coverage of the stochastic approximation theory.

MULTISTAGE PROBLEMS

In this section, we demonstrate how the ideas that we discuss in the section titled “Two-Stage Problems” can be extended to more complex resource management problems that take place over multiple time periods. We consider a setting where we have a set of resources that can be used to serve the demands that arrive randomly over time. At each time period, we observe the realization of the demand arrivals, and we need to decide which demands we should serve and to which locations we should reposition the unused resources. The objective is to maximize the total expected profit over a finite planning horizon.

The problem takes place over the planning horizon $\mathcal{T} = \{1, \dots, \tau\}$. For notational brevity, we assume that the travel times between all pairs of locations are one time period. We continue using $\mathcal{L}$ to denote the set of locations in the transportation network. To capture the decisions, we let x_{ijt} be the number of resources that we reposition from location i to j at time period t and y_{it}^k be the number of demands of type k that we serve by using a resource at location i at time period t . The cost of repositioning one resource from location i to j is c_{ij} . If we serve a demand

of type k by using a resource at location i , then we generate a revenue of p_i^k , and the resource ends up at location δ^k at the next time period. Similar to the convention that we use in the section titled “Two-Stage Problems,” if it is infeasible to serve a demand of type k by using a resource at location i , then we assume that $p_i^k = -\infty$. We use the random variable D_t^k to represent the number of demands of type k that arrive at time period t . We assume that the demand arrivals at different time periods are independent. We let r_{it} be the number of resources available at location i at the beginning of time period t . We note that $\{r_{i1} : i \in \mathcal{L}\}$ is a part of the problem data, whereas $\{r_{it} : i \in \mathcal{L}\}$ for $t \in \mathcal{T} \setminus \{1\}$ is determined by the decisions at time period $t - 1$.

We can formulate the problem as a dynamic program by using $r_t = \{r_{it} : i \in \mathcal{L}\}$ as the state variable at time period t . Letting $\mathbf{1}(\cdot)$ be the indicator function, and using $x_t = \{x_{ijt} : i, j \in \mathcal{L}\}$ and $y_t = \{y_{it}^k : i \in \mathcal{L}, k \in \mathcal{K}\}$ to capture the decisions and $D_t = \{D_t^k : k \in \mathcal{K}\}$ to capture the demand arrivals at time period t , the set of feasible decisions and state transitions are given by

$$\begin{aligned} \mathcal{X}(r_t, D_t) = & \left\{ (x_t, y_t, r_{t+1}) : \sum_{j \in \mathcal{L}} x_{ijt} \right. \\ & \left. + \sum_{k \in \mathcal{K}} y_{it}^k = r_{it}, \quad \forall i \in \mathcal{L} \right\} \quad (10a) \end{aligned}$$

$$\begin{aligned} & \sum_{i \in \mathcal{L}} x_{ijt} + \sum_{i \in \mathcal{L}} \sum_{k \in \mathcal{K}} \mathbf{1}(\delta^k = j) \\ & \times y_{it}^k - r_{j,t+1} = 0, \quad \forall j \in \mathcal{L}; \quad (10b) \end{aligned}$$

$$\sum_{i \in \mathcal{L}} y_{it}^k \leq D_t^k, \quad \forall k \in \mathcal{K}; \quad (10c)$$

$$x_{ijt}, y_{it}^k, r_{j,t+1} \in \mathbb{Z}_+, \quad \forall i, j \in \mathcal{L}, k \in \mathcal{K}. \quad (10d)$$

Constraint (10a) ensures that the number of resources that we reposition between different locations and use to serve the demands does not violate the resource availabilities. Constraint (10b) computes the number of resources available at different locations at the beginning of the next time period. Constraint 10c ensures that the number of demands that we serve does not exceed the demand arrivals. We can

find the optimal policy by computing the value functions $\{\bar{V}_t(\cdot) : t \in \mathcal{T}\}$ through the optimality equation

$$\begin{aligned} \bar{V}_t(r_t) = & \mathbb{E} \left\{ \max_{(x_t, y_t, r_{t+1}) \in \mathcal{X}(r_t, D_t)} - \sum_{i \in \mathcal{L}} \sum_{j \in \mathcal{L}} c_{ij} x_{ijt} \right. \\ & \left. + \sum_{i \in \mathcal{L}} \sum_{k \in \mathcal{K}} p_i^k y_{it}^k + \bar{V}_{t+1}(r_{t+1}) \right\}, \end{aligned}$$

with the boundary condition that $\bar{V}_{\tau+1}(\cdot) = 0$ [59]. The optimality equation above involves a high dimensional state variable, which makes it difficult to compute the value functions for all possible values of the vector r_t . This difficulty is further compounded by the fact that the decisions (x_t, y_t) in the problem above are high dimensional vectors, and we take an expectation that involves the high dimensional demand arrivals D_t . Powell [60] uses the term “three curses of dimensionality” to refer to the difficulty due to the sizes of the state, decision, and demand vectors.

It turns out that all of the ideas in the section titled “Two-Stage Problems” can be extended to multistage problems. For economy of space, we only show extensions of the deterministic linear program and the separable projective approximations. Cheung and Powell [29] extend the demand relaxation strategy and Topaloglu [47] extends the supply relaxation strategy to multistage problems.

Deterministic Linear Program

Assuming that all demand arrivals take on their expected values, we can approximate the total expected profit over the planning horizon by using the optimal objective value of the problem

$$\begin{aligned} \max - & \sum_{t \in \mathcal{T}} \sum_{i \in \mathcal{L}} \sum_{j \in \mathcal{L}} c_{ij} x_{ijt} \\ & + \sum_{t \in \mathcal{T}} \sum_{i \in \mathcal{L}} \sum_{k \in \mathcal{K}} p_i^k y_{it}^k \quad (11a) \end{aligned}$$

$$\text{subject to } \sum_{j \in \mathcal{L}} x_{ijt} + \sum_{k \in \mathcal{K}} y_{it}^k - r_{it} = 0,$$

$$\forall i \in \mathcal{L}, t \in \mathcal{T}; \quad (11b)$$

$$\begin{aligned} \sum_{i \in \mathcal{L}} x_{ijt} + \sum_{i \in \mathcal{L}} \sum_{k \in \mathcal{K}} \mathbf{1}(\delta^k = j) y_{it}^k \\ - r_{j,t+1} = 0, \quad \forall j \in \mathcal{L}, t \in \mathcal{T} \setminus \{\tau\}; \end{aligned} \quad (11c)$$

$$\sum_{i \in \mathcal{L}} y_{it}^k \leq \mathbb{E}\{D_t^k\}, \forall k \in \mathcal{K}, t \in \mathcal{T}; \quad (11d)$$

$$\begin{aligned} x_{ijt}, y_{it}^k, r_{it} \in \mathbb{R}_+, \forall i, j \in \mathcal{L}, \\ k \in \mathcal{K}, t \in \mathcal{T}. \end{aligned} \quad (11e)$$

Constraints (11b), (11c) and (11d) in problem 11 are respectively analogous to constraints (3b), (3c) and (3d) in problem 3. In the problem above, our understanding is that the values of the decision variables $\{r_{i1} : i \in \mathcal{L}\}$ are fixed by the number of resources that we have at different locations at the beginning of the planning horizon. By following the same hindsight approach that we use in the section titled “Deterministic Linear Program,” it is possible to show that the optimal objective value of problem 11 provides an upper bound on the optimal total expected profit. Such an upper bound becomes useful when we want to assess the optimality gaps of suboptimal approximation strategies.

We need minor modifications in problem 11 when we use this problem to make the resource repositioning and demand service decisions dynamically over time. In particular, if we are at time period t and the demand arrivals at the current time period are given by $\{D_t^k : k \in \mathcal{K}\}$, then we replace the right side of constraint (11d) for time period t with the current realization of the demand arrivals $\{D_t^k : k \in \mathcal{K}\}$. For the other time periods, we keep using the expected values of the demand arrivals. In addition, we fix the values of the decision variables $\{r_{it} : i \in \mathcal{L}\}$ to reflect the number of resources that we have at different locations at the current time period. Finally, we replace the set of time periods $\mathcal{T}$ with $\{t, \dots, \tau\}$ so that we only concentrate on the time periods in the future. Solving problem 11 after these modifications ensures that the decisions that we obtain for time period t are

feasible for the current state of the resources and the current realization of the demand arrivals.

Separable Projective Approximations

The idea behind the separable projective approximations is to construct approximations to the value functions by using sampled trajectories of the system. In particular, assuming that we have a set of approximations $\{\hat{V}_t(\cdot) : t \in \mathcal{T}\}$ to the value functions $\{\bar{V}_t(\cdot) : t \in \mathcal{T}\}$, if the number of resources at different locations is given by r_t and the realization of the demand arrivals is given by D_t , then we can make the decisions at time period t by solving the problem

$$\begin{aligned} \max_{(x_t, y_t, r_{t+1}) \in \mathcal{X}(r_t, D_t)} & - \sum_{i \in \mathcal{L}} \sum_{j \in \mathcal{L}} c_{ij} x_{ijt} \\ & + \sum_{i \in \mathcal{L}} \sum_{k \in \mathcal{K}} p_i^k y_{it}^k + \hat{V}_{t+1}(r_{t+1}). \end{aligned}$$

Therefore, repeated solutions of the problem above for the successive time periods in the planning horizon would allow us to simulate the trajectory of the system under a particular realization of the demand arrivals. The challenge is to use the information that we obtain from the simulated trajectories of the system to update and improve the value function approximations.

We use the separable functions $\{V_t^{SPA}(\cdot) : t \in \mathcal{T}\}$ as our value function approximations. Similar to the development in the section titled “Separable Projective Approximations,” each one of these value function approximations is of the form $V_t^{SPA}(r_t) = \sum_{i \in \mathcal{L}} V_{it}^{SPA}(r_{it})$, where $V_{it}^{SPA}(\cdot)$ is a single dimensional, piecewise linear and concave function with points of nondifferentiability being a subset of integers. Letting Q be the total number of available resources, we can characterize $V_{it}^{SPA}(\cdot)$ by the sequence of slopes $\{v_{it}(q) : q = 0, \dots, Q-1\}$, where $v_{it}(q)$ is the slope of $V_{it}^{SPA}(\cdot)$ over the interval $[q, q+1]$.

The updating procedure in the section titled “Separable Projective Approximations,” together with the idea of simulating the trajectories of the system, immediately provides an iterative method that can be

- Step 1. Initialize the iteration counter by letting $n = 1$. Initialize the approximations $\{V_{it}^{SPA,1}(\cdot) : i \in \mathcal{L}\}$ to arbitrary piecewise linear and concave functions with points of nondifferentiability being a subset of integers.
- Step 2. Sample a realization of the demand arrivals over the whole planning horizon and denote this sample by $\{\hat{D}_t^{k,n} : k \in \mathcal{K}, t \in \mathcal{T}\}$.
- Step 3. Simulate the evolution of the system under the current demand arrivals and the current value function approximations.
- Step 3.a. Initialize the time by letting $t = 1$. Initialize the state of the resources $\hat{r}_1^n = \{\hat{r}_{i1}^n : i \in \mathcal{L}\}$ to reflect the initial state.
- Step 3.b. Solve the problem
- $$\tilde{V}_t(\hat{r}_t^n, \hat{D}_t^n) = \max_{(x_t, y_t, r_{t+1}) \in \mathcal{X}(\hat{r}_t^n, \hat{D}_t^n)} - \sum_{i \in \mathcal{L}} \sum_{j \in \mathcal{L}} c_{ij} x_{ijt} + \sum_{i \in \mathcal{L}} \sum_{k \in \mathcal{K}} p_i^k y_{it}^k + \hat{V}_{t+1}^{SPA,n}(r_{t+1}),$$
- to obtain the optimal solution $(\hat{x}_t^n, \hat{y}_t^n, \hat{r}_{t+1}^n)$. Compute and store $\hat{v}_t^n = \tilde{V}_t(\hat{r}_t^n + e_i, \hat{D}_t^n) - \tilde{V}_t(\hat{r}_t^n, \hat{D}_t^n)$ for all $i \in \mathcal{L}$.
- Step 3.c. Increase t by one. If $t < \tau$, then go to Step 3.b.
- Step 4. Using α^n to denote the step size parameter at iteration n , update the value function approximations by letting $V_{it}^{SPA,n+1}(\cdot) = \mathcal{U}\left(V_{it}^{SPA,n}(\cdot), \hat{r}_{it}^n, \hat{v}_{it}^n, \alpha^n\right)$ for all $i \in \mathcal{L}, t \in \mathcal{T}$. Increase n by one and go to Step 2.

Figure 2. An iterative approach to construct separable value function approximations when there are multiple time periods in the planning horizon.

used to construct separable value function approximations. We describe this method in Fig. 2. In Step 1, we initialize the value function approximations. In Step 2, we sample a realization of the demand arrivals over the whole planning horizon. In Step 3, we simulate the evolution of the system under the current demand arrivals and the current value function approximations. In Step 4, we update the value function approximations to obtain the value function approximations that we use at the next iteration. The updating procedure $\mathcal{U}(V_{it}^{SPA,n}(\cdot), \hat{r}_{it}^n, \hat{v}_{it}^n, \alpha^n)$ in this step is identical to the one that we describe in the section titled “Separable Projective Approximations.”

A FLEXIBLE MODELING FRAMEWORK

The resource management problems that we have considered so far are relatively simplistic. In particular, the only distinguishing characteristic of a resource is its location, whereas the only distinguishing characteristic of a demand is its type. Our motivation for working with somewhat simplistic resource management problems is that such problems allow us to demonstrate the crucial algorithmic issues more clearly, but practical resource management problems can easily take on much more complex characteristics. For example, a driver resource in a driver scheduling application can be described by its inbound location, time to reach the inbound location, duty time within

the shift, days away from home, vehicle type, and home domicile. Conceptually, we can model such a complex resource by using multiple indices in our decision and state variables to capture the different attributes of the resource, but this approach would clearly be too cumbersome. In this section, we describe a flexible paradigm that is useful for modeling complex resource management problems.

Resources

To represent the resources, we let $\mathcal{A}$ be the attribute space of the resources. Roughly speaking, the attribute space represents the set of all possible states of a particular resource. We refer to each element of the attribute space as an attribute vector. We let r_{at} be the number of resources with attribute vector a at time period t . For example, if we assume that the set of locations is $\mathcal{L}$, the set of vehicle types is $\mathcal{V}$ and the travel time between any pair of locations is bounded by $\bar{V}$, then the attribute space for the vehicles in a simple dynamic fleet management application is $\mathcal{A} = \mathcal{L} \times \mathcal{V} \times \{0, 1, \dots, \bar{T}\}$. A vehicle with the attribute vector $a = (a_1, a_2, a_3) = (\text{New York}, \text{Large}, 4) \in \mathcal{A}$ is a vehicle of type large that is inbound to New York and will reach New York in four time periods. We can access the number of resources with attribute vector a at time period t by referring to r_{at} . This implies that we can lump the resources with the same attribute vector together and treat them as indistinguishable.

We use a similar approach to represent the demands. We let $\mathcal{B}$ be the attribute space of the demands and D_{bt} be the number of demands with attribute vector b at time period t . For example, if the set of expedition options is $\mathcal{E}$, then the attribute space for the demands may be $\mathcal{B} = \mathcal{L} \times \mathcal{L} \times \mathcal{E}$. A demand with the attribute vector $b = (b_1, b_2, b_3) = (\text{New York}, \text{Delaware}, \text{Express}) \in \mathcal{B}$ is an express demand with origin location New York and destination location Delaware. It may be not possible to serve an express demand from New York to Delaware by using a vehicle in New Jersey, but if the demand is not express, then it may be the case that a vehicle in New Jersey can serve

this demand. Therefore, the characteristics of the demand may dictate the feasible resource assignments.

Decisions

We use two classes of decisions. The class of decisions $\mathcal{D}^R$ captures the repositioning decisions, whereas the class of decisions $\mathcal{D}^S$ captures the demand service decisions. We let $\mathcal{D} = \mathcal{D}^R \cup \mathcal{D}^S$ to capture the set of all decision classes and refer to each element of $\mathcal{D}$ as a decision. For example, we may have $\mathcal{D}^R = \mathcal{L} \times \mathcal{L}$, and the decision $d = (d_1, d_2) = (\text{New York}, \text{Delaware}) \in \mathcal{D}^R$ may represent the decision to reposition a resource from New York to Delaware. Similarly, we may have $\mathcal{D}^S = \mathcal{B}$, and the decision $d = (b_1, b_2, b_3) \in \mathcal{D}^S = \mathcal{B}$ may represent the decision to serve a demand with the attribute vector b . It is reasonable to assume that for each decision $d \in \mathcal{D}^S$, there exists an attribute vector $b_d \in \mathcal{B}$ such that the decision d corresponds to serving a demand with attribute vector b_d .

We use x_{adt} to denote the number of resources with attribute vector a that we modify by using decision d at time period t . If we modify a resource with attribute vector a by using decision d at time period t , then we generate a profit contribution of c_{adt} . If it is not feasible to apply decision d on a resource with attribute vector a , then we capture this situation by letting $c_{adt} = -\infty$. In this case, we can capture the decisions at time period t by $x_t = \{x_{adt} : a \in \mathcal{A}, d \in \mathcal{D}\}$, the state of the resources by $r_t = \{r_{at} : a \in \mathcal{A}\}$, and the state of the demands by $D_t = \{D_{bt} : b \in \mathcal{B}\}$.

Optimization Problem

The set of feasible decisions at time period t is given by

$$\mathcal{X}(r_t, D_t) = \left\{ x_t : \sum_{d \in \mathcal{D}} x_{adt} = r_{at} \right. \\ \left. \forall a \in \mathcal{A} \right\} \quad (12a)$$

$$\sum_{a \in \mathcal{A}} x_{adt} \leq D_{b_d, t}, \forall d \in \mathcal{D}^S; \quad (12b)$$

$$x_{adt} \in \mathbb{Z}_+ \forall a \in \mathcal{A}, d \in \mathcal{D}, \quad (12c)$$

where we use the fact that for each decision $d \in \mathcal{D}^S$, there exists an attribute vector $b_d \in \mathcal{B}$ such that the decision d corresponds to serving a demand with attribute vector b_d . We note that constraints (12c) and (12b) are respectively analogous to constraints (10a) and (10c). We capture the outcome of applying a decision d on a resource with attribute vector a by defining

$$\delta_{a'}(a, d) = \begin{cases} 1 & \text{if applying the decision } d \text{ on} \\ & \text{a resource with attribute} \\ & \text{vector } a \text{ transforms the} \\ & \text{resource into a resource} \\ & \text{with attribute vector } a'; \\ 0 & \text{otherwise.} \end{cases}$$

The precise definition of $\delta_{a'}(a, d)$ is naturally dependent on the physics of the problem and how the system reacts to decisions. Using the definition above, we can write the dynamics of the resources as

$$r_{a,t+1} = \sum_{a' \in \mathcal{A}} \sum_{d \in \mathcal{D}} \delta_{a'}(a, d) x_{a'dt}, \quad \forall a \in \mathcal{A},$$

which is analogous to constraint (10b). The implicit assumption in the definition of $\delta_{a'}(a, d)$ is that the current attribute vector of the resource and the decision that we apply on the resource deterministically give the future attribute vector of the resource. This is indeed the case in many resource management applications, but there may be settings with random travel times and equipment failures where this assumption is not necessarily satisfied.

A Markovian policy π is a collection of decision functions $\{X_t^\pi(\cdot) : t \in \mathcal{T}\}$ such that each $X_t^\pi(\cdot)$ maps the state of the system (r_t, D_t) to a decision vector $x_t \in \mathcal{X}(r_t, D_t)$. Our goal is to find a policy that maximizes the total expected profit over the planning horizon. In other words, using $C_t(x_t) = \sum_{a \in \mathcal{A}} \sum_{d \in \mathcal{D}} c_{adt} x_{adt}$ to denote the total profit associated with the decisions x_t at time period t and Π to denote the set of all Markovian policies, we want to solve the problem

$$\sup_{\pi \in \Pi} \mathbb{E} \left\{ \sum_{t \in \mathcal{T}} C_t(X_t^\pi(r_t, D_t)) \right\}.$$

The formulation above provides a compact representation of the resource management problem that we are interested in, but it does not help from an algorithmic perspective. In particular, it is impossible to make a direct search over a reasonably broad class of policies Π . Therefore, the modeling framework that we describe in this section is useful for communicating the problem, but the actual solution requires a concrete algorithmic approach such as the ones described in the sections titled “Two-Stage Problems” and “Multistage Problems.”

The modeling framework that we describe in this section is due to Shapiro [61] and Powell *et al.* [62]. These works are intended to capture a broad class of resource management problems arising from a variety of application settings, and their presentation is significantly larger in scope than ours. Powell [60] uses this modeling framework to come up with a sound formulation for general dynamic programs, with a particular emphasis on the evolution of information over time. Shapiro and Powell [63] demonstrate how to use the modeling framework within the context of several algorithmic approaches to decompose large-scale resource management problems. Powell *et al.* [64], Powell and Topaloglu [65], Powell *et al.* [66], Powell and Topaloglu [22], Schenk and Klabjan [20], and Simao *et al.* [67] apply the modeling framework to dynamic fleet management, military airlift operations, express package routing, and driver scheduling problems. We note that the presentation in this article uses demands as the only source of uncertainty. The driver scheduling application in Ref. 67 is particularly interesting as it models a variety of sources of uncertainty, such as random travel times, equipment failures, and driver availability.

NUMERICAL ILLUSTRATIONS

In this section, we numerically compare the performances of the different approximation strategies that we describe in the sections titled “Two-Stage Problems” and “Multistage Problems.” Our goal here is to give a feel

for the relative performances of the different approximation strategies, rather than to present a full-scale experimental study.

Numerical Results for Two-Stage Problems

In this section, we provide numerical results for two-stage problems. The test problems that we use in our experimental setup have the same structure as the problem that we describe in the section titled “Two-Stage Problems.” We generate ten locations uniformly over a 100×100 region. Using $d(i, j)$ to denote the Euclidean distance between locations i and j , the cost of repositioning a resource from location i to j is given by $d(i, j)$. We have ten demand types and each demand type is associated with a particular location. The revenue from using a resource at location i to serve a demand type that is associated with location j is given by $200 - \rho \times d(i, j)$, where ρ is a parameter that we vary. As ρ gets larger, it becomes less profitable to serve a demand type that is associated with a particular location by using a resource at another location. In our computational experiments, we vary the coefficient of variation of the demand random variables and the parameter ρ . In particular, letting v be the coefficient of variation of the demand random variables, we label our test problems by the pair $(v, \rho) \in \{0.25, 0.5, 0.75, 1.0\} \times \{0.25, 0.5, 0.75, 1.0\}$. We note that the numerical results that we present in this section do not appear in the previous literature.

We test the performances of the approximation strategies described in the sections titled “Deterministic Linear Program,” “Decomposition by Demand Relaxation,” “Decomposition by Supply Relaxation,” and “Separable Projective Approximation,” which we respectively refer to as DLP, DDR, DSR, and SPA. DLP immediately provides a set of first stage decisions $\{\hat{x}_{ij} : i, j \in \mathcal{L}\}$. On the other hand, DDR, DSR, and SPA provide value function approximations that are all separable functions of the form $\sum_{i \in \mathcal{L}} \hat{V}_i(\cdot)$. To obtain a set of first stage decisions $\{\hat{x}_{ij} : i, j \in \mathcal{L}\}$, DDR, DSR, and SPA replace $\bar{V}(r)$ in the objective function of problem 2 with $\sum_{i \in \mathcal{L}} \hat{V}_i(r_i)$ and solve this problem. For DDR, DSR, and SPA, it is possible

to show that each one of $\{\hat{V}_i(\cdot) : i \in \mathcal{L}\}$ is a piecewise linear and concave function with points of nondifferentiability being a subset of integers. In this case, we can formulate problem 2 with the value function approximation $\sum_{i \in \mathcal{L}} \hat{V}_i(\cdot)$ as a minimum cost network flow problem [68]. A set of first stage decisions allow us to compute the cost that we incur at the first stage. In addition, we can compute the number of resources at different locations at the beginning of the second stage by $\hat{r}_j = \sum_{i \in \mathcal{L}} \hat{x}_{ij}$ for all $j \in \mathcal{L}$. To check the quality of the first stage decisions, we replace the right side of constraint (1b) in problem 1 with $\{\hat{r}_i : i \in \mathcal{L}\}$ and solve this problem for many realizations of demand arrivals. In this way, we approximate the total expected revenue in the second stage. The total expected profit is the difference between the total cost and the total expected revenue in the two stages.

Table 1 summarizes our numerical results. The first column in this table shows the problem characteristics by using the pair (v, ρ) . In the sections titled “Deterministic Linear Program,” “Decomposition by Demand Relaxation,” and “Decomposition by Supply Relaxation,” we show that DLP, DDR, and DSR provide upper bounds on the optimal total expected profit. The second, third, and fourth columns in Table 1 respectively show the upper bounds obtained by these three strategies. The fifth and sixth columns show the percent gap between the upper bounds obtained by DDR and the remaining two strategies. DDR provides the tightest upper bounds and we use it as a reference point. The seventh, eighth, ninth, and tenth columns respectively show the total expected profits obtained by DLP, DDR, DSR, and SPA. Finally, the eleventh, twelfth, and thirteenth columns show the percent gaps between the total expected profits obtained by SPA and the remaining three strategies. SPA generally obtains the highest total expected profits and we use it as a reference point.

Our results indicate that the gaps between the upper bounds obtained by DDR and the other two strategies can be quite significant. We observe that the gaps between the upper bounds get larger as the coefficient of

variation of the demand random variables increases and as it becomes more costly to serve a demand type from a location that is not associated with the demand type. We use the coefficient of variation as a proxy for the level of uncertainty in the problem, and the problem clearly becomes more difficult as the level of uncertainty increases. Furthermore, the substitution possibilities become more scarce as it becomes more costly to serve a demand type from a location that is not associated with the demand type. Therefore, we also expect the problem to be more difficult as ρ gets larger. These observations imply that the upper bounds provided by DDR are especially attractive for the test problems that we expect to be more difficult. The total expected profits obtained by DDR, DSR, and SPA are quite close to each other but SPA provides a small, consistent improvement over DDR and DSR. It is interesting that although the upper bounds obtained by DDR are significantly tighter than those obtained by DSR, the performances of DDR and DSR are quite similar. As a matter of fact, DSR appears to provide slightly better performance than DDR. For both DDR and DSR, we choose the Lagrange multipliers by using the dual solution to problem 3. Similar to our observations for the upper bounds, the gaps between the total

expected profits obtained by DLP and the remaining three strategies get larger as the coefficient of variation of the demand random variables increases or as it becomes more costly to serve a demand type from a location that is not associated with the demand type. Therefore, using a model that addresses the uncertainty in the system becomes especially beneficial for the test problems that we expect to be more difficult.

Numerical Results for Multistage Problems

In this section, we provide numerical results for multistage test problems. The results that we provide are taken from Ref. 18. In our experimental setup, we generate one base test problem and modify its different attributes to come up with test problems with different characteristics. In the base test problem, we have 20 locations. The problem takes place over a planning horizon of 60 time periods. The cost of repositioning a resource from location i to j is given by $c \times d(i, j)$, and we use $c = 4$. For each demand type k , there is an origin location o^k and destination location δ^k , and a demand of type k can only be served by a resource at location o^k . The revenue from serving a demand of type k is $p \times d(o^k, \delta^k)$, and we use $p = 5$. We have a total of 200 resources at our disposal.

Table 2. Numerical Results for Multistage Problems.

Problem	Total Expected Profit		SPA versus DLP
	DLP	SPA	
Base	155,378	166,913	6.91
$ \mathcal{L} = 10$	190,681	198,391	3.89
$ \mathcal{L} = 40$	162,132	172,021	5.75
$\sum_{i \in \mathcal{L}} r_{i1} = 100$	88,766	98,083	9.50
$\sum_{i \in \mathcal{L}} r_{i1} = 400$	250,448	263,775	5.05
$c = 1.6$	220,115	232,262	5.23
$c = 8.0$	113,671	121,617	6.53

Table 2 summarizes our numerical results. The first column in this table shows the problem characteristics that we modify to obtain different test problems. The first test problem corresponds to the base case. The second and third test problems have different number of locations in the transportation network. The fourth and fifth test problems have different number of resources. Finally, the sixth and seventh test problems have different repositioning costs. The second and third columns in Table 2 show the total expected profits obtained by DLP and SPA. The fourth column shows the percent gap between the total expected profits obtained by DLP and SPA. Our numerical experiments in the previous section indicate that SPA performs at least as well as DDP and DSR. Therefore, we only compare the performance of SPA with that of DLP.

The computational results indicate that the performance gap between DLP and SPA can be on the order of 4–10%. One trend worth mentioning is that the performance gaps increase as we have fewer resources at our disposal. In particular, the performance gap between SPA and DLP increases from 5.05% to 6.91% as the number of resources decreases from 400 to 200. Similarly, the performance gap between SPA and DLP increases from 6.91% to 9.50% as the number of resources decreases from 200 to 100. We consistently observed this trend in all of our numerical experiments. As the resources become more scarce, we need to allocate the resources more carefully, and SPA appears to do a better job of allocating scarce resources.

CONCLUSIONS

In this article, we describe a variety of modeling and solution approaches for transportation resource management problems. The solution approaches that we propose either build on deterministic linear programming formulations, or formulate the problem as a dynamic program and use tractable approximations to the value functions. We use two classes of methods to construct value function approximations. The first class of methods relax certain constraints in the dynamic programming formulation of the problem by associating Lagrange multipliers with them. In this case, we can solve the relaxed dynamic program by concentrating on one location at a time. The second class of methods use a stochastic approximation idea along with sampled trajectories of the system to iteratively update and improve the value function approximations. Our numerical experiments indicate that the models that explicitly address the randomness in the demand arrivals can provide significant benefits.

INTRODUCTION

Methods for estimating and forecasting travel demands draw on a number of different disciplines, making use of optimization methods embedded in econometric as well as mathematical programming frameworks, and using microsimulation and agent-based modeling to generate travel activity patterns from the ground up for entire regional populations of travelers and freight movers. These methods are now well represented in software programs which in today's computers generate demand estimates in anything from a few seconds to a few hours, depending on the size of the task at hand. In this article, we describe the most common travel demand modeling approaches, the nature of the solution methods used, and the types of data used to fit or "calibrate" them to real-world conditions. A feature of the travel demand literature over the past half century has been the variety of methods that have been applied, with method selection often determined by the nature and quality of available data sources as well as by specific solution needs. Current models can be categorized in a number of ways. One obvious distinction is between passenger demand and freight demand models, although both use similar solution methods. From a practitioners' standpoint the following classification also proves useful:

- location-specific, time series-based demand models;
- cross-sectional modeling of origin-to-destination travel, usually broken down by travel mode and/or travel route, as well as by trip purpose or class of commodity shipped.

A few examples of combined time series/cross-sectional travel demand models have also been developed, but to date have seen limited use due principally to limited data with which to calibrate them.

A second important distinction is between what has been called the *trip based approach*, which has been the dominant approach in practice since the 1950s, and the more recent and increasingly popular "activity-based approach" to travel demand modeling. The differences between these two approaches are brought out below.

TIME SERIES-BASED DEMAND MODELS

Time series data is often used to develop forecasts of the demand for specific transportation facilities such as airports [1–3] and seaports [4,5], as well as for high volume links within a transportation network [6,7]. The empirical data used in these models may span a few weeks, a few months, or a few years of prior passenger, freight, or vehicular traffic volume data, and the forecast may be short term, covering the next few weeks or months, or long term, extending projections a number of years into the future. The historical data set may include data for a single facility or location or may combine data from a number of different locations, such as vessel arrival or departure data collected for all of the ports in a given region or country. In some cases, a simple univariate time series model is used, based solely on projecting a past trend in traffic growth or decline forward in time; or a multivariate, causal model may be applied that relates the temporal trend in facility or regional demand to

temporal trends in a number of explanatory variables: such as trends in travel prices, disposable incomes, industrial output, and growth in the size of selected traveling populations. In some instances [8], time series data from one modal activity (e.g., number of offloaded seaport containers) has been used to forecasts travel demand for another mode (e.g., the number of trucks serving a seaport).

Past studies offer a variety of methods to choose from, including simple growth factor methods, multiple regressions, exponential smoothing, Kalman filters, multinomial tobits and probits, and artificial neural network models, as well as a variety of autoregressive integrated moving average (ARIMA) models, in the tradition of Box and Jenkins [9], including variable (VARIMA) and seasonal (SARIMA) models. Commercial software is available to estimate model parameters, with most solutions based on well-established techniques for either minimizing a residual sum-of-squares function or maximizing a likelihood function associated with the observed time series. Similar techniques have been used in both passenger and freight demand forecasting.

CROSS-SECTIONAL, TRIP-BASED DEMAND MODELING

Once the issue becomes one of forecasting the demand for multiple origin-to-destination (O-D) travel movements, and the geographic context moves away from a single facility or travel corridor, then data limitations play a major role in model selection, as they have done in model development over the past 50 years. In particular, when we enter the realm of regional transportation planning, we are dealing with the estimation and forecasting of hundreds, even thousands, of spatially explicit O-D movements within, as well as into, out of, and through a planning region (see the popular textbooks by Meyer and Miller [10] and Ortuzar and Willumsen [11]).

The high costs of collecting this sort of O-D data on personal or business travel activities means that most demand models are based on the responses provided by a sample of households or companies to a travel

questionnaire, from which are developed a hopefully representative set of daily trip rates (trip frequencies) and trip lengths, broken down by trip purpose or commodity class, as well as data on the modes and sometimes also the routes selected. While this approach can work quite well for the purpose of understanding current activity rates and even the geographic range of individual travel activity patterns, it is necessarily only a surrogate for a proper behavioral analysis of how such travel decisions as mode and destination choices evolve over time, and as households and businesses themselves evolve. A preferred method for capturing such behavioral connections is to carry out panel surveys, in which the same establishment (i.e., a household or a business) is resurveyed one or more times after a suitable time interval: the challenge being to avoid attrition in the sample, especially as the time interval increases [12]. Such sampling typically occurs in two or more “waves” and as such introduces an element of time-series modeling into the estimation process. To date, however, only a limited number of such panel data sets have been collected and applied. Most planning models make use of travel surveys that draw a different sample of respondents from one survey to the next, often at an interval of 5 or more years. As a result, most applications of regional travel demand models have placed a good deal of reliance on the variability caused by a combination of differences in a respondent’s household or company structure along with differences in responses created by the different geographic locations and site-specific conditions they find themselves dealing with.

Disaggregate Behavioral Models

Discrete choice (or “logit”) models based on utility maximization theory are commonly used to represent how individuals or companies make travel and shipment decisions. Discrete choice models are used to predict the probability a decision maker will choose one alternative among a finite set of mutually exclusive and collectively exhaustive alternatives. A decision maker can represent an individual, a group of individuals, a government, a corporation, and so on. Discrete

choice models are used to estimate and forecast the total demand for a specific travel alternative as the sum of a set of individual traveler or (where freight is involved) shipper choices, usually based on traveler or shipper perceptions of the utility of one alternative over another.

Utility is a scalar index of value that is a function of attributes and/or individual characteristics. Utility represents the “value” an individual places on different attributes and captures how individuals make trade-offs among these attributes. Individuals are assumed to select the alternative that has the maximum utility. Alternative i is chosen if the utility of individual n obtains from alternative i , U_{ni} , is greater than the utility for all other alternatives. This utility U_{ni} , has an observed component, V_{ni} , and an unobserved component, commonly referred to as an *error term*, ε_{ni} . Formally, $U_{ni} = V_{ni} + \varepsilon_{ni}$, where

$$V_{ni} = \beta' x_{ni}.$$

Specific choice probabilities for different discrete choice models are obtained by imposing different assumptions on the distribution of these error terms and/or by assuming that β varies across decision makers. The assumption that unobserved error components are independently and identically distributed (iid) and follow a Gumbel distribution with mode zero and scale one, $\varepsilon \sim \text{iid } G(0, 1)$, results in the binary logit (in the case of two alternatives) or the multinomial logit model, or MNL, (in the case of more than two alternatives) [13]. Under these assumptions, MNL choice probabilities are given as

$$P_{ni} = \frac{\exp(V_{ni})}{\sum_{j \in C_n} \exp(V_{nj})}, \quad (1)$$

where C_n is the set of alternatives (or choice set) faced by individual n . The assumption that the error terms are iid $G(0, 1)$ is advantageous in the sense that the choice probability takes on a closed-form expression that is computationally simple. However, the same assumption imposes several restrictions on the binary logit and MNL models. The first

key restriction is the independence of irrelevant alternatives (IIA), a property which states that the ratio of choice probabilities P_{ni}/P_{nj} for $i, j \in C_n$ is independent of the attributes of any other alternative. In terms of substitution patterns, this means a change or improvement in the utility of one alternative will draw share proportionately from all other alternatives. In many applications, this may not be a realistic assumption. For example, in mode choice model applications, one would expect that bus would compete more with other public transit modes than auto. Consequently, much of the research in the travel demand modeling community over the past 30–40 years has been focused on incorporating more flexible substitution patterns. The most commonly used model in practice that helps relax the IIA property while maintaining a closed-form expression for choice probabilities is the nested logit (NL) model [14,15]. Dozens of other models have been developed for travel demand modeling applications, including those belonging to the generalized “hierarchical” or “nested” logit (GNL, generalized nested logit) class [16] and/or the network generalized extreme value (NetGEV) class [17]. Garrow [18] provides an extensive review of these models in her text and focuses on applications of these models to the airline industry. Ben-Akiva and Lerman [19], Train [20], and Koppelman and Bhat [21] are other key introductory texts on applying discrete choice models for travel demand applications.

The second key limitation of MNL models is that the β parameters represent “average” population values. The multinomial probit (MNP) model [22] was one of the first discrete choice models that was used to incorporate more flexible substitution patterns and/or random taste variation. However, due to computational limitations, the ability to use the probit model was limited. It was not until the past decade that an alternative to the probit model, namely the mixed logit model, was introduced.

Conceptually, the mixed logit model is identical to the MNL model except that the parameters of the utility functions for mixed models can vary across individuals, alternatives, and/or observations. However,

like the probit model, this added flexibility comes at a cost—choice probabilities can no longer be expressed in closed form. Due to improvements in computational power, however, it is now feasible to use mixed logit models for travel demand modeling applications. Indeed, the number of publications using mixed logit models has expanded exponentially since 2003 and mixed logit models have been applied in numerous other transportation contexts spanning activity-based planning and rescheduling behavior models [23–25], mode choice models [26,27], residential location/relocation decisions [28], and consideration of physical activity in choice of mode [29].

Similar models have recently become popular with freight modelers. Some authors have also combined traditionally separate choice dimensions (see the section titled “Aggregate, Four-Step Planning Models”). For example, Train and Wilson [30] used an MNL logit to analyze the choice of mode by agricultural product shippers, making use of both revealed and respondent state preference data to calibrate their model. Jiang *et al.* [31] use an NL model to estimate the demand for alternative freight modes in which all for-hire modes are compared within the same nest, and their averaged, inclusive value utility was then compared with the private carriage (in Europe own-account) modal service option. A heteroscedastic extreme value (HEV) choice model has also been used in freight mode choice applications [32,33]. See Jeffs and Hills [34] for a discussion of the explanatory variables often found to be significant in freight mode choice.

Aggregate, Four-Step Planning Models

In the United States, each metropolitan area as well as each state develops databases and models to estimate current, or baseline, traffic volumes using its major transportation facilities. It then links these estimates to regional economic activity and demographic forecasts in order to predict future traffic flows. These forecasts are used in turn to inform the investment of large sums of public money in expanding or improving transportation services within the region.

For the past 50 years or so, this process has been supported, notably in large urban or metropolitan regions, by the four-step transportation planning model shown in Fig. 1. Most commonly applied to passenger, or personal travel forecasting, this approach begins by modeling the frequency with which households engage in travel, estimating the number of trips generated daily for a number of different trip purposes. This usually involves separate model calibrations, for example, for commuting to work, shopping, traveling to school, and making personal business, social and recreational trips; with a distinction also common between home-based and non-home-based trips. The four sequential modeling steps can be represented in very general terms as

Trip (or Freight) Generation:

$$O_{ip} = F(X_{ip})$$

and Attraction:

$$D_{jp} = F(X_{jp}) \quad (2a)$$

Trip (or Freight) Distribution (Flow):

$$T_{ijp} = F(O_{ip}, D_{jp}, c_{ijp}) \quad (2b)$$

Modal Split:

$$T_{ijpk} = F(T_{ijp}, g_{ijpk}, c_{ijpk}) \quad (2c)$$

Route Assignment:

$$\Sigma_p T_{ijpkr} = T_{ij^*kr} = F(T_{ij^*k}, g_{ij^*kr}, c_{ij^*kr}) \quad (2d)$$

where $F()$ means “a function of,” and where i = a trip origin ($i = 1, 2, \dots, I$), j = a trip destination ($j = 1, 2, \dots, J$), O_i = the number of trip origins out of i , D_j = the number of trip destinations into j , T = a daily (or annual) measure of travel demand, and T_{ijpkr} , for example, refers to the number of trips taken daily (or annually) from i to j for purpose p by mode k and route r ; c = transportation costs, and c_{ijkr} for example, refers to the cost of transporting a passenger or unit of freight from i to j by mode k on route r . Finally, X_i , X_j , and g refer to matrices of explanatory variables associated with specific steps in the flow estimation process.

Figure 1. Four-step transportation planning model.

The principal reason for the sequential nature of this approach was the failure of early modeling efforts to capture each of these four policy relevant aspects of travel demand within a single model calibration step: with the variables best explaining mode choice, for example, differing from those yielding good estimates of the other three choices. Efforts to do so, usually referred to as *direct demand models* in the literature, are still used, and have been found to be valuable and cost effective in specific situations, such as for sketch planning purposes and/or for use in small community demand forecasting [35,36]. For the most part, these models use standard multiple regression software. However, most applications in the United States today employ the above four-step process when developing regional travel forecasts.

For the purpose of producing planning and policy relevant outputs, each step in the process is executed at an aggregate, or traffic analysis zone (TAZ) level, with the largest metropolitan regions broken down into hundreds of TAZs for the purpose of estimating O-D flows between all TAZ pairs. In practice, such TAZs are often equated with Census blocks, block-groups, or tracts, in order to make use of federally supplied estimates of the number of households and businesses

within each TAZ. At the statewide level in the United States, and at the national level in many smaller countries, such TAZs may be equated with counties. Within metropolitan areas, the focus is on automobile and truck flows, as well as public transit bus and rail movements. At the statewide level, other nonhighway modes enter the picture, notably air, rail, and water transport.

Variants on the same four-step modeling process have also been used to forecast daily and annual freight flow volumes, with the focus on truck freight movements over urban and intercity highways, and using a three-step process where modal split is not required, but adding an additional submodel where flows are estimated initially not in number of trips but in number of tons of different commodities shipped, which then need to be translated into the number of vehicle (i.e., truck) trips using suitable tons/truck loading factors. A popular functional form for all four modeling steps, for both passenger and freight demand modeling, is the logit model, with linear and log-linear regressions also popular for the trip generation stage. However, most regional transportation planning models then merge the truck freight and passenger automobile flows to produce passenger car equivalent (pce) O-D

flow matrices, in which the larger trucks are allocated pce values much greater than 1.0 before assigning them to the same highway network. Where this loading leads to high levels of traffic volume to capacity (v/c) ratios, the use of congestion-sensitive route choice algorithms have become the norm, notably traffic route assignments based on Wardrop's [37] user optimal equilibrium principle. In this approach travelers select their routes in such a way that their aggregate flow patterns lead to identical travel times between all routes used to travel between any given O-D pair of places.

Finally, a look at Figure 1 also shows an important feedback loop between the trip destination, mode and route choice submodels. By iterating in this manner, and maintaining convexity in the submodel solutions, it is possible to bring the flows and costs at each modeling step to a stable solution: such that no further significant changes occur in either O-D costs or O-D trip volumes, that is, bringing destination, mode, and route choices to a cost-flow balance. Other feedback loops can be tried, and this feedback loop has not always been applied in the past. However, extension of this procedure to trip generation is rarely attempted using traditional model formulations, largely because daily trip frequencies are relatively insensitive to trip cost differences at the level of spatial aggregation to which these planning models are typically applied. Indeed, the entire four-step sequential modeling process has received growing criticism from a number of quarters over the past four decades, not only for its limited behavioral basis but also for its lack of a cohesive conceptual framework. One response has been the rapid evolution of the disaggregate demand models reviewed above. A second response has been to develop more closely integrated, "combined" choice models that work through economically based equilibrium formulations of the entire flow modeling process [38]. The text by Oppenheim [39] describes and links both approaches together. These combined models use technical advances in nonlinear mathematical programming solution techniques, model formulations based on variational inequalities, and computationally

efficient solution methods tied to link-node, path-based network formulations of not only the physical traffic flows themselves but also of the entire process of identifying and tracking travel choices through numerous decision making steps.

Mathematical Programming Formulations

The logit discrete choice model can also be derived as an optimization problem, which in its aggregate, planning level application has well-known convex programming solution. Texts by Wilson [40], Erlander and Stewart [41], and Lee [42], among others, explore these formulations. For example, for a set of annual (or daily) trip volumes, T_{ij} , between origin locations $i = 1, 2, \dots, I$ and destination locations $j = 1, 2, \dots, J$, Wilson [40] shows that the following *entropy maximizing* trip distribution (destination) model

$$\text{Max } L(T) = -\sum_i \sum_j (T_{ij}/T) \ln(T_{ij}/T) \quad (3)$$

subject to:

$$\begin{aligned} \sum_j T_{ij} &= O_i \quad \text{for all } i \quad \text{and} \quad \sum_i T_{ij} \\ &= D_j \quad \text{for all } j \end{aligned} \quad (4)$$

$$\begin{aligned} \text{cbar} &= (1/T)^* \sum_i \sum_j T_{ij}^* c_{ij} \\ \text{and all } T_{ij} &\geq 0 \end{aligned} \quad (5)$$

was solved by the following *doubly constrained* spatial interaction model:

$$T_{ij} = A_i^* B_j^* O_i^* D_j^* \exp(-\beta^* c_{ij}), \quad (6)$$

where O_i = the volume of travel (e.g., number of trips) generated by TAZ i , D_j = the volume of travel attracted to TAZ j , and A_i and B_j are two sets of matrix "balancing factors" given as

$$A_i = 1 / \left[\sum_j B_j^* D_j^* \exp(-\beta^* c_{ij}) \right] \quad \text{for all } i \quad (7)$$

and

$$B_j = 1 / \left[\sum_i A_i^* O_i^* \exp(-\beta c_{ij}) \right] \quad \text{for all } j, \quad (8)$$

which, via iterative application, satisfy the trip end constraints given by Equation (4). Here β represents the sensitivity of travelers (or in the case of freight movements, shippers) to additional travel cost. Applying a suitable nonlinear search method, a value of β is sought that satisfies the system's average cost constraint above, while also meeting the two sets of trip end constraints. A little thought here also shows that setting all B_j 's (A_i 's) to a value of 1.0 yields a trip origination (trip attraction) constrained model in aggregate logit form.

Subsequently, Erlander [43] showed how this model can also be restated as an equivalent cost-minimization model of the form

Minimize $C(T)$

subject to:

$$\sum_j T_{ij} = O_i \quad \text{for all } i \quad \text{and}$$

$$\sum_i T_{ij} = D_j \quad \text{for all } j$$

$$L(T) = -\sum_i \sum_j (T_{ij}/T) \ln (T_{ij}/T) \geq L_0,$$

$$\text{and all } T_{ij} \geq 0,$$

where L_0 = a minimum acceptable level of trip dispersion.

Numerous extensions of this sort of approach have been used since the 1970s to formulate and solve increasingly more elaborate travel demand (O–D flow inclusive) models, including the “joint” solution of optimal O–D flow and traffic route assignment models [43] as well as jointly optimized O–D, mode, and route choice solutions in freight [44] as well as passenger travel. These approaches also set the table for the solution of much broader optimization problems that include optimal land use as well as optimal travel pricing mechanisms within their spatially explicit price-versus-volume based equilibrium solutions [42,45].

Similar programming models have also been applied to freight demand estimation and forecasting, but with the T_{ij} 's increasingly solved for in terms of tons shipped, rather than number of vehicle trips, notably by combining Leontief's input–output approach to capturing interindustry interactions with the spatial interaction models of the type represented by Equations (6)–(8)

above to create interregional or multiregional input–output models of commodity flows. When combined with logit or other discrete choice model of mode selection (e.g., of truck vs rail vs waterway vs intermodal truck–rail or truck–water transport), these modeling frameworks are now beginning to be applied in statewide freight demand forecasting in the United States as well as in nationwide freight demand forecasting in Europe and elsewhere (see the review of freight demand models by Southworth [46]).

ACTIVITY-BASED APPROACHES, MICROSIMULATION, AND AGENT-BASED MODELING TOOLS

All of the modeling approaches described in the section titled “Cross-Sectional, Trip Based Demand Modeling” have been applied to forecasting the number of passenger or freight trips associated with a region's population distribution and its travel generating land use patterns. In doing so, these trips are effectively abstracted from the often complex set of family influenced decisions being made by individual travelers and the company logistics-based decisions being made by shippers of goods. In effect, the approach has proved to be a very cost-effective way of simplifying the travel demand process: by treating nontravel decisions as largely exogenous to the production of trips. Also, beginning in the 1950s [47], but only gaining any noticeable level attention by the 1970s, was a more behaviorally attractive but at the same time more conceptually as well as computationally demanding *activity-based approach* (ABA) to travel demand modeling. In this approach, travel activities are more closely linked to the complex scheduling decisions associated with a good deal of household travel, or as McNally and Rindt [47, Section 3.1] put it: “The ABA takes as the basic unit of analysis the travel-activity pattern, defined as the revealed pattern of behavior represented by travel and activities (both in-home and non-home) over a specific time period (often a single day).” Hence an individual's single day travel activity schedule might look something like that shown in Fig. 2, in this instance for a two-adult-one-child family.

Figure 2. A daily multitrip chaining example for a three-person household.

A little thought about the many variables that might affect such a daily activity pattern indicates that this sort of modeling can become quite complex. Key improvements associated with an ABA approach over the traditional four-step process are the ability to model explicitly the multistop, tour-based structure of much of today's out-of-home travel, and the ability to link the purpose behind a trip more closely to both in- and out-of-home daily household activities. Microsimulation methods then allow these concepts to be implemented computationally. In particular, Monte Carlo-based methods are being used to associate specific attributes (of the traveler, the vehicle, the cargo, the geography) with each trip simulated, using repeated sampling from predefined statistical distributions to create a synthetic population of travelers and/or their trips. This is done by first of all building individual traveler profiles, sometimes termed *synthetic travelers*, by drawing sample traveler characteristics from statistical distributions of, for example, different age, income, and employment groups. These travelers are then assigned a specific travel activity pattern, typically a daily pattern. When the simulator is asked to select the traveler's trip frequency, mode, route, or destination, this

means drawing from a set of probabilities that have themselves already been modeled using either logit or similar demand models of the type discussed above, or using a rule-based activity scheduling algorithm [48]. In addition, it is common to use continuous duration models with activity-based models, for example, for modeling the temporal dimension of trip departure time choice. Once generated, these individual traveler activity patterns can then be aggregated to produce an estimate (and subsequently a forecast) of the number of trips taking place between any pair of locations, by vehicle type (and by vehicle occupancy if the method used is sophisticated enough to match up trips involving more than one family member). Besides this natural aggregation property, microsimulation is also an especially efficient method for representing sequential events, allowing a natural incorporation of system dynamics. This includes the generation of multitrip, multipurpose daily tours or "trip chains" of the sort shown in Fig. 2.

Miller [49] provides a review and a brief history of the best known microsimulation models in use in both North America and Europe. See also Kitamura *et al.* [50]. In the United States this includes the Transportation Analysis and Simulation System,

or TRANSIMS¹: a model, or more correctly modeling system, developed over the past decade by Los Alamos National Laboratory and its contractors for the US Department of Transportation. The modeling approach and its many software modules are downloadable and is extensively documented [51]. Reinforcing the microsimulation theme, the approach includes the use of cellular automata methods to track the detailed movements of, and interactions between, individual vehicles as they move down the highway. Among other benefits, this allows greater attention to computing such impacts as vehicle emissions that are heavily influenced by the nature of stop-go traffic movements. In Europe, the Multiagent Transport Simulation Toolkit (MATSim)² is a similarly complex, and agent-based (see below) microsimulation modeling system [52] which was also developed around an activity-based approach to household travel forecasting. The ALBATROSS model [53] uses a sequential decision process to generate the daily activity schedules of individual travelers, simulating for a given day which activities are conducted, when (start time), for how long (duration), where (location), with whom, and, if traveling is involved, the transport mode used and chaining of trips engaged in. This makes a household's daily activity schedule the unit of prediction, with some activity timing and duration decisions modeled as continuous, rather than discrete choices, subject to sensible daily space-time constraints. Unlike the traditional four-step aggregate demand models described in section titled "Aggregate, Four-Step Planning Models" earlier, these different ABA modeling systems each use their own unique sequential and iterative modeling structures, and the mix of both conceptual and computational methods used to construct a household's daily travel activity pattern continues to evolve.

Microsimulation also lends itself well to the construction of freight movements. In Canada, Hunt [54] described the use of

microsimulation to generate daily multistop pickup and delivery truck tours based on the output from logit regression models which are used to select such attributes as the next stop's trip purpose, its location, and departure time interval. The approach can also be used to build vehicle shipments from the ground up, beginning with the selection of the origination point, the size, and nature of the cargo to be moved, through the detailed scheduling as well as routing of the vehicles used to move it, while also recognizing any physical constraints on its transportation [55]. Microsimulation is also proving to be useful in the modeling of freight through complete multistage product supply chains (Boerkamps *et al.* [56] in the Netherlands; Wisetjindawat *et al.* [57] in Japan, in which the movement dynamics may play themselves out over many days or even weeks at a time). In Massachusetts, Xu *et al.* [55] use microsimulation to model the routing of trucks over transportation networks as part of a much broader approach to freight modeling that incorporates a pseudo-real-time information simulator linked to a complete supply chain decision making simulator based on a very formal mathematical treatment of the freight movement problem as a variational inequality by Nagurney *et al.* [58]. See also Kuzmyak [59] for a recent review of forecasting metropolitan commercial and freight travel.

In taking on this added detail, which also relaxes the limitations on the number of household or industry classes and trip purposes used in traditional four-step planning models, an ABA approach can become computationally very time consuming. This is especially true if thousands, or even millions, of such patterns need to be simulated in support of project assessments and other planning applications. Fortunately, the tremendous advances in computational speeds over the past five decades have now provided a practical means of addressing this problem. Raney *et al.* [60] discuss this issue, noting that rule-based computer codes of the type used to simulate individual traveler decisions do not vectorize easily, and therefore do not run efficiently on traditional vector supercomputers—but that they do

¹http://tmip.fhwa.dot.gov/community/user_groups/~transims

²<http://www.matsim.org>

however run well on modern workstation architectures, which makes traffic simulations ideally suited for clusters of PCs such as Beowulf clusters.

Some of the most promising opportunities associated with microsimulation in the near future are likely to be tied to recent advances in travel data collection, and specifically to vehicle and cargo tracking technologies such as global positioning satellites (GPS) and radio frequency identification devices (RFIDs). These "IT"-based data collection methods are bringing a much needed visibility to the step-by-step movements of both people and goods. This includes the digital recording and storage of detailed personal travel diaries as well as electronic freight data manifests, each creating a new opportunity to establish both the realism and statistical reliability of microsimulation-based travel forecasting methods.

A natural adjunct to both ABA and microsimulation modeling entering the travel demand literature with increasing frequency is an approach known as *agent-based modeling* (ABM). Given a set of allowable actions and possible strategies for action, ABM allows a population of autonomous agents, such as a group of households or freight shippers or receivers (= agents) to interact among themselves to determine how much and what types of travel to engage in, with individual agent behaviors based on an agent's current status, its objective, and its history of past actions. Like microsimulation, ABA supports a bottom-up approach to estimating travel activity patterns, and as such seems well suited to travel activity systems in which individual tripmaking behaviors can be aggregated, sometimes yielding unexpected system-level *emergent behaviors* [61]. This point gets directly to a key weakness in current trip-based aggregate passenger and freight demand models: the difficulty we have in linking our forecasts of travel activity to causal mechanisms and hence, by implication, to policy instruments based on the expected behavior of passengers, shippers, carriers, receivers, warehousemen, and third party logistics agents. Rindt *et al.* [62] and Zhang and Levinson [63] describe early efforts to develop agent-based passenger

demand models. Venkat and Wakeland [64] and Hunt and Stefan [65] describe the use of ABM modeling to simulate commercial freight movements. Takama and Preston [66] combine agent-based modeling with discrete choice binary logit, mixed nested logit (MNL), and Markov queueing models to simulate the effects of road user charges on mode choice and parking behavior. In doing so, they also demonstrate the growing tendency of modelers to solve demand estimation and forecasting problems using a mix of solution methods.

SUMMARY

The past half-century has seen considerable technical as well as conceptual innovation in travel model design, calibration, and application. One notable line of advance has been the recognition that modeling approaches with very different origins, in economic/utility theory, in system optimization, in categorically based statistical analysis, in spatial interaction theory, and in agent-based and rule-based microsimulation, can all contribute to a better understanding as well as better means of estimating the demand for travel. Just how well these and other methods contribute to better forecasts remains to be seen and needs to be supported by a retention of historical data sources that will allow modelers to look back, as well as forward, and learn from their past efforts.

TREewidth, TREE DECOMPOSITIONS, AND BRAMBLES

ARIE M.C.A. KOSTER
Lehrstuhl II für Mathematik,
RWTH Aachen University,
Aachen, Germany

INTRODUCTION

The notions of tree decomposition and treewidth were introduced by Robertson and Seymour [1] in a long series of papers to prove Wagner's conjecture. Let $G = (V, E)$ be an undirected graph consisting of a set of vertices V and a set of edges E . A tree decomposition of a graph G is a pair $(\{X_i, i \in I\}, T = (I, F))$ with $X_i \subseteq V$, $i \in I$ and $T = (I, F)$ a tree (i.e., an acyclic connected graph), such that

- (TD1) $\bigcup_{i \in I} X_i = V$;
- (TD2) for all $vw \in E$, there is an $i \in I$ with $v, w \in X_i$; and
- (TD3) for all $v \in V$, $\{i \in I : v \in X_i\}$ forms a connected subtree of T .

The *width* of a tree decomposition $(\{X_i, i \in I\}, T = (I, F))$ is $\max_{i \in I} |X_i| - 1$. The *treewidth* $\tau(G)$ of G is the minimum width over all tree decompositions of G .

Figure 1 shows a graph and a tree decomposition of the graph. The property TD3 is sometimes called the *interpolation property*. Furthermore, note that (TD1) is obsolete if G has no isolated vertices.

Several equivalent notions for treewidth have been studied over time, such as partial k trees, dimension, and k -decomposability. A graph has treewidth at most k , if and only if it is a partial k -tree, if and only if the dimension of G is at most k , if and only if G is k -decomposable. See Ref. 2 for further details. The related notions of *pathwidth* and *branchwidth* are briefly described at the end of this article.

One further equivalent notion is *bramble*, which first appeared in Ref. 3 under the name *screen*. We follow the terminology of Reed [4]. Two subsets $W_1, W_2 \subseteq V$ are said to *touch* if they have a vertex in common or E

contains an edge between them ($W_1 \cap W_2 \neq \emptyset$ or there is an edge $\{w_1, w_2\} \in E$ with $w_1 \in W_1, w_2 \in W_2$). A set $\mathcal{B}$ of mutually touching connected vertex sets is called a *bramble*. A subset of V is said to *cover* $\mathcal{B}$ if it is a hitting set for $\mathcal{B}$ (i.e., a set which intersects every element of $\mathcal{B}$). The *order* of a bramble $\mathcal{B}$ is the minimum size of a hitting set for $\mathcal{B}$. The *bramble number* $b(G)$ of G is the maximum order of all brambles of G .

Theorem 1 [3]. $\tau(G) = b(G) - 1$.

For a short proof of this theorem, we refer to Ref. 5. A class of graphs for which the bramble of maximum order can be constructed easily is the class of grid graphs. It is folklore that an x by x grid has treewidth x ; see, for example, Fig. 2 for a bramble of order $x + 1$: We have one set that contains all vertices on the bottom row, one set that contains all vertices in the last column except the last one, and $(x - 1)^2$ crosses, each consisting of the first $x - 1$ vertices of one of the first $x - 1$ rows and the first $x - 1$ vertices of one of the first $x - 1$ columns. A set that covers the bramble must contain at least $x - 1$ vertices to cover the crosses, and one vertex in each of the other two sets.

Treewidth has gained its importance by many *parameterized complexity* results [6,7]. A combinatorial optimization problem is *fixed-parameter tractable* (FPT) if there exists an exact algorithm to solve the problem in which running time is polynomial in the size of the input, except for one **fixed** parameter. Treewidth is such a parameter; for example, the weighted independent set problem can be solved in $O(2^k \cdot n)$ time, assuming $n = |V|$ and a tree decomposition of width k is part of the input [8]. Hence, maximum weighted independent sets can be solved in polynomial (linear) time if the treewidth of the graph is bounded by a constant (whereas the problem is $\mathcal{NP}$ -complete in general).

In subsequent sections, we discuss tree decomposition-based algorithms, the computation of treewidth in theory and practice, lower bounds on the treewidth including

Figure 1. Graph and a tree decomposition with width 3.

Figure 2. Illustrating a bramble of a grid.

brambles, and related notions.

TREE DECOMPOSITION-BASED ALGORITHMS

In general, an FPT algorithm for a problem that takes treewidth as a parameter has the following structure:

1. A tree decomposition (X, T) of G is found; the width of this tree decomposition is small (bounded by a constant, not necessarily optimal), see the next section for further details.

2. A dynamic programming algorithm is executed on the tree decomposition; for each node of the tree decomposition, a table is computed. For a decision problem, the table for the root of the tree T shows the answer. (For construction variants of problems, additional book-keeping and a construction step follow the run of the dynamic programming algorithm.)

For many $\mathcal{NP}$ -complete problems like independent set [8], Hamiltonian circuit, chromatic index [9], or Steiner tree [10] the above procedure results in a polynomial-time algorithm if defined on a graph of bounded treewidth. The dynamic programming algorithm works in a bottom-up fashion, that is, the tree $T = (I, F)$ is rooted at some node and the algorithm first computes results for the leaves of this rooted tree, next for the parents of the leaves and so on, until the root is reached.

To simplify explanation and implementation of the dynamic program, the tree decomposition is usually converted to a *nice tree decomposition*. In a nice tree decomposition, each node $i \in I$ is of one of the four following types:

- **Leaf:** Node i is a leaf of T , and $|X_i| = 1$.

- **Join:** Node i has exactly two children, say j_1 and j_2 and $X_i = X_{j_1} = X_{j_2}$.
- **Introduce:** Node i has exactly one child, say j , and there is a vertex $v \in V$ with $X_i = X_j \cup \{v\}$.
- **Forget:** Node i has exactly one child, say j , and there is a vertex $v \in V$ with $X_j = X_i \cup \{v\}$.

It is not hard to see that if G has treewidth at most k , then G also has a nice tree decomposition of width at most k which has $O(n)$ tree nodes. Such a nice tree decomposition can be built in linear time, given a (not nice) tree decomposition [11].

A graph $G_i = (V_i, E_i)$ is associated with each node $i \in I$. V_i is the union of all bags X_j , with $j = i$ or j a descendant of i in T , and $E_i = E \cap (V_i \times V_i)$ is the edge set induced by V_i .

For each node $i \in I$, a table, with all (in)feasible solutions for G_i and which are different with respect to X_i , is computed. The table for a leaf node is computed by just enumeration of the possible solutions. For a join node, the tables of the two children are joined by identifying the solutions. For an introduce node, the solutions are extended with the new vertex. Finally, for a forget node, all solutions that are identical with respect to X_i are identified by a single one (with best objective). A more detailed description of such a dynamic programming algorithm for a practical problem can be found in Refs 12 and 13 for frequency assignment in wireless networks.

Tree decomposition-based algorithms have been shown to be of practical interest; for example, for the inference problem for probabilistic networks in decision support systems, the traveling salesman problem TSP [14], and the partial constraint satisfaction problems with binary relations [12,13] (with frequency assignment and MAX SAT as special cases).

In real-life applications, memory consumption is a major concern as the tables contain an exponential number of entries. Techniques to reduce the memory requirements have been proposed in Ref. 15.

COMPUTING TREewidth: THEORY

The formal decision problem of treewidth asks whether there exists a tree decomposition with width at most k for some integer $k > 0$. If k is part of the input, $\mathcal{NP}$ -completeness was proved by Arnborg *et al.* [16]. If k may be considered a constant, not part of the input, the best algorithm has been given by Bodlaender [17] and checks in linear time whether or not a tree decomposition with width at most k exists, and if so, finds such a tree decomposition. The $O(n)$ notation for this algorithm however hides a huge constant coefficient that obstructs its practical computational value. An experimental evaluation by Röhrig [18] revealed that the algorithm is computationally intractable, even for k as small as four.

Graphs with treewidth of at most four can be characterized directly or indirectly: $\tau(G) = 1$ if and only if G is a forest, $\tau(G) \leq 2$ if and only if its biconnected components are series-parallel graphs [19]. Arnborg and Proskurowski [20] gave six reduction rules that reduce G to the empty graph if and only if $\tau(G) \leq 3$ (subsets suffice for $\tau(G) = 1$ and 2). Sanders [21] provided a linear-time algorithm for testing $\tau(G) \leq 4$.

Besides forests and series-parallel graphs, the complexity of treewidth is known for some special classes of graphs (by presenting either a polynomial-time algorithm or an $\mathcal{NP}$ -completeness proof). In particular, the treewidth of bipartite graphs is $\mathcal{NP}$ -complete, since every graph can be converted to a bipartite graph with the same treewidth by subdividing its edges (replacing the edge by two edges incident to a new vertex). We refer the interested reader to two surveys on the topic by Bodlaender [22,23]. Most remarkable in this context is that, so far, the complexity of treewidth for planar graphs is unknown, whereas for branchwidth a polynomial-time algorithm exists. Lapoire [24] and Bouchitté *et al.* [25] proved that the treewidth of a planar graph and of its geometric dual differ by, at most, one. The result is generalized in Ref. 26 to a difference of $\ell + 1$ for (hyper)graphs on a surface of genus ℓ .

The treewidth of a graph can also be found

by dynamic programming [27], resulting in an exact (but exponential) algorithm. The best-known exact algorithm computes the treewidth of a general graph with n vertices in $O(1.7347^n)$ if exponential space can be used [28], and $O(2.6151^n)$ with polynomial space [29].

Given a graph G with $\tau(G) = k$, the best approximation algorithm by Feige *et al.* [30] provides a tree decomposition of width at most $O(k\sqrt{\log k})$ (i.e., a $O(\sqrt{\log k})$ approximation). So far, a constant approximation algorithm is neither known nor is it proven that no such algorithm exists.

COMPUTING TREewidth: PRACTICE

Most results presented in the previous section are of theoretical interest only: the computational complexity hides huge constant coefficients that make the algorithms impractical for actual computation of treewidth. So far, only the reduction rules for treewidth, at most three, have been proved to be of practical use in preprocessing the input graph. However, in all those cases where the treewidth is larger than three, we typically have to turn to heuristics without any performance guarantee. The survey articles of Refs 31 and 32 have been dedicated to this topic. An accompanying website [33] allows experiments with some of the algorithms. Here, we briefly review preprocessing, exact algorithms, and upper-bound heuristics.

Preprocessing

The reduction rules of Ref. 20 not only reduce graphs of treewidth at most three to the empty graph, but can also be used as a preprocessing technique to reduce the size of general graphs. In Ref. 34, the rules have been adapted and extended such as to preprocess general graphs. Computational experiments have shown that significant reductions in the graph size can be achieved by these rules.

The above-mentioned preprocessing rules emphasize the removal of vertices from the graph. Another way to reduce the complexity of finding a good tree decomposition is the splitting of the input graph into smaller

graphs for which we can construct a tree decomposition independently. In Ref. 35, so-called *safe separators* are introduced for this purpose. A separator S is a set of vertices whose removal disconnects a graph G . Let V^i , $i = 1, \dots, p$ ($p \geq 2$), induce the connected components of $G - S$. On each of the connected components $G[V^i]$, a graph G^i is defined as $G[V^i \cup S] \cup K(S)$, where $K(S)$ denotes a complete graph, or *clique*, on S . If $\tau(G) = \max_{i=1, \dots, p} \tau(G^i)$, then S is called *safe* for treewidth. In particular, clique separators (i.e., S induces a clique) and almost-clique separators (i.e., S contains a $|S| - 1$ clique) are safe. Experiments have shown the effectiveness of safe separators [35].

Exact Algorithms

Although treewidth is $\mathcal{NP}$ -hard in general, there have been a couple of attempts to tackle the problem by exact approaches. Shoikhet and Geiger [36] implemented a modified version of the $O(n^{k+2})$ algorithm by Arnborg *et al.* [16]. A branch-and-bound algorithm based on vertex-ordering has been proposed by Gogate and Dechter [37]. In Ref. 27 a dynamic programming algorithm has been developed, based on the Held–Karp algorithm for TSP. Due to its exponential space requirement, only relatively small graphs can be solved exactly this way.

Upper-Bound Heuristics

Most heuristics without a performance guarantee are of a constructive nature: according to some principle, we construct a tree decomposition from scratch. Improvement heuristics as well as metaheuristics are less frequently exploited.

The construction heuristics are typically based on the equivalence of the treewidth problem with the problem of finding a triangulation of G with minimum–maximum clique size. A *triangulated* or *chordal* graph is a graph in which every cycle of length of at least four has a chord. A *triangulation* of a graph $G = (V, E)$ is a chordal graph $H = (V, F)$ with $E \subseteq F$.

Lemma 1. *Let G be a graph, and let $\mathcal{H}$ be the set of all triangulations of G . Then,*

$\tau(G) = \min_{H \in \mathcal{H}} \omega(H) - 1$, where $\omega(H)$ is the size of the maximum clique in H .

Thus, if G is triangulated, then $\tau(G) = \omega(G) - 1$, otherwise we have to find a triangulation of H with small maximum clique size. Several algorithms exist to check whether G is triangulated or to construct a triangulation of G . Examples of such algorithms are the *lexicographic breadth first search* (LEX) recognition algorithm by Rose *et al.* [38], the *maximum cardinality search* (MCS) by Tarjan and Yannakakis [39] and variants of those algorithms that guarantee to find a *minimal* triangulation (i.e., no $e \in F$ can be removed without losing the triangulation property) known as *LEX-M*, [38] and *MCS-M* [40], respectively. See Refs 31 and 41 for some experimental results for LEX-P, MCS, and LEX-M.

The *minimal fill-in* problem is another problem that is studied in relation to triangulation of graphs. The minimum fill-in of a graph is the minimum number of edges to be added to a graph such that the resulting graph is chordal/triangulated. This problem is known to be $\mathcal{NP}$ -hard [42], but it is not difficult to think of two heuristics. The first one is a greedy algorithm: select repeatedly the vertex for which the fill-in among its neighbors is minimized, turn its neighbors into a clique, and remove that vertex. This algorithm is called *Greedy Fill-In* (GFI) or simply the minimum fill-in algorithm in some articles. The *Greedy Degree* (GD) or simply minimum degree algorithm, repeatedly selects the vertex of minimum degree and turns its neighbors into a clique before removing the vertex. These algorithms typically provide very good upper bounds for both fill-in and treewidth in reasonable time. For computations and further heuristics, we refer to the survey article by Bodlaender and Koster [31].

TREewidth LOWER BOUNDS AND BRAMBLES

Another way to approach the treewidth problem is to bound the treewidth from below. In

this way, no tree decomposition is obtained but a good estimate of the span of the true treewidth of a graph can be obtained. Moreover, high-quality lower bounds are helpful within branch-and-bound approaches to bound the size of the search tree. An extensive survey on lower bounds for treewidth will be published in Ref. 43. Here we review the most important developments, with a focus on brambles.

First of all, it is easy to see that every lower-bound algorithm for treewidth can be extended by taking the maximum of the lower bound over all subgraphs or minors: given an optimal tree decomposition for G and H a subgraph (minor) of G , then we can construct a tree decomposition with equal or better width for H by removing vertices from the bags that are not part of the subgraph (minor) and replacing contracted vertices by their new vertex.

By Theorem 1, a bramble $\mathcal{B}$ of order k implies $\tau(G) \geq k - 1$. So, finding a high order bramble immediately implies getting a good lower bound for the treewidth. Unfortunately, determining the order of a bramble, is also $\mathcal{NP}$ -hard; it follows directly from the $\mathcal{NP}$ -hardness of the minimum hitting set problem [44] by taking a complete graph G and the collection of subsets as the bramble.

In Ref. 45, two algorithms for constructing a bramble of high order are presented, one for general graphs and one for planar graphs. Both algorithms aim at finding large grid minors in G , exploring the so-called *Grid Minor Theorem*.

Theorem 2 [46,47]. *There exists a function $f(r)$ such that any graph of treewidth at least $f(r)$ has a $r \times r$ grid graph as a minor. The best-known function $f(r)$ for general graphs is superexponential.*

In addition, a hitting set of a $r \times r$ grid graph can be computed easily (Fig. 2). The algorithms partition the vertex set in connected subsets representing the *vertical* connections. These subsets are connected by *horizontal* vertex-disjoint paths. By contracting a part of the subsets, grid minors in minors of G can be found. The lower bound provided by the size of the bramble in such a

grid minor is a lower bound on the treewidth of G by the above-mentioned result.

The grid minor algorithm for planar graphs is shown to give a lower bound for treewidth that is at most a constant factor away from the optimum. For both algorithms, extensive computational experiments are reported showing that the algorithms often give excellent lower bounds, in particular when applied to (close to) planar graphs.

Recently, Chapelle *et al.* [48] present an algorithm for graphs with treewidth larger than k to construct a bramble of size $k + 2$ in $O(n^{k+4})$. Brambles are also used to find minimal forbidden minors for treewidth [49].

Besides brambles, lower bounds can be computed in a variety of ways. The probably widest known lower bound is given by the maximum clique size. This can be seen by Lemma 1: the maximum clique of G will be part of a clique in any triangulation of G .

Scheffler [50] proved that every graph of treewidth at most k contains a vertex of degree at most k . Stated differently, the minimum degree $\delta(G)$ is a lower bound on the treewidth of a graph. Typically, this lower bound is of no real interest as the minimum degree can be arbitrarily small. Even if the preprocessing rules of the previous section have been applied before, only $\delta(G) \geq 3$ can be guaranteed.

As mentioned before, improvements on this bound can be obtained by taking subgraphs or minors of G . The *degeneracy* $\delta D(G)$ of G is the maximum minimum degree over all subgraphs of G , and hence is a lower bound on $\tau(G)$ (and can be computed by repeatedly removing the minimum degree vertex). Independently, Bodlaender *et al.* [51] and Gogate and Dechter [37] combined the minimum degree lower bound with taking minors. The so-called *contraction degeneracy* $\delta C(G)$ is defined as the maximum minimum degree over all minors of G . In Ref. 51 it is proven that computing $\delta C(G)$ is $\mathcal{NP}$ -hard and computational experiments are presented by applying tiebreakers to the following algorithm: repeatedly contract a vertex of minimum degree to one of its neighbors and record the maximum encountered. Significantly better lower bounds than the degeneracy are obtained this way. In Ref. 52, further

results for contraction degeneracy are discussed, showing for example that $\delta C(G) \leq 5 + \gamma(G)$, where $\gamma(G)$ is the *genus* of G .

Ramachandramurthi [53,54] introduced the parameter

$$\gamma_R(G) = \min \left(n - 1, \min_{\substack{v,w \in V, v \neq w, \\ \{v,w\} \notin E}} \max(d(v), d(w)) \right),$$

and proved that this is a lower bound on the treewidth of G . Note that $\gamma_R(G) = n - 1$ if and only if G is a complete graph on n vertices. If G is not complete, then $\gamma_R(G)$ is determined by a pair $\{v, w\} \notin E$ with $\max(d(v), d(w))$ as small as possible. From its definition it is clear that $\gamma_R(G) \geq \delta_2(G) \geq \delta(G)$, where $\delta_2(G)$ is the second smallest degree appearing in G (note $\delta(G) = \delta_2(G)$ if the minimum degree vertex is not unique). All these three lower bounds can be computed in polynomial time.

Lucena [55] proved that with the MCS upper-bound algorithm, a lower-bound $MCSLB(G)$ on the treewidth can be obtained. Bodlaender and Koster [56] proved that determining whether $MCSLB(G) \leq k$ for some $k \geq 7$ is $\mathcal{NP}$ -complete and presented computational results by constructing MCS-orderings using tiebreakers for the decisions within the MCS algorithm.

Also the lower bounds $\delta_2(G)$, $\gamma_R(G)$, and $MCSLB(G)$ can be computed over all minors. Bodlaender and Koster [51] studied the combination of $MCSLB(G)$ and taking minors, whereas Koster *et al.* [57] studied the combination of $\delta_2(G)$ and $\gamma_R(G)$ and taking minors. In practice, $\delta_2 C(G)$ and $\gamma_R C(G)$ are only marginally better (if at all) than the lower bounds computed for the contraction degeneracy.

Finally, improved lower bounds for treewidth can be obtained by the following result.

Theorem 3 [58]. *Let $G = (V, E)$ be a graph with $\tau(G) \leq k$ and $\{v, w\} \notin E$. If there exist at least $k + 2$ vertex-disjoint paths between v and w , then $\{v, w\} \in F$ for every triangulation H of G with $\omega(H) \leq k$.*

Hence, if we know that $\tau(G) \leq k$ and there exist $k + 2$ vertex disjoint paths between v

and w , adding $\{v, w\}$ to G should not hamper the construction of a tree decomposition with small width. Clautiaux *et al.* [59] explored this result by first computing a lower bound ℓ on the treewidth of G by any of the above methods (e.g., $\ell = \delta C(G)$) and next assuming $\tau(G) \leq \ell$ and adding edges $\{v, w\}$ to G for which there exist $\ell + 2$ vertex-disjoint paths in G . Let G' be the resulting graph. Now, if it can be shown that $\tau(G') > \ell$ by a lower-bound computation on G' , our assumption that $\tau(G) \leq \ell$ is false. Hence, $\tau(G) > \ell$ or stated equally $\tau(G) \geq \ell + 1$: an improved lower bound for G is determined. This procedure can be repeated until it is not possible anymore to prove that $\tau(G') > \ell$ (which of course, does not imply that $\tau(G') = \ell$). In Ref. 51 the above-described approach is nested within a minor-taking algorithm, resulting in the best known lower bounds for most tested graphs [60]. In many cases, optimality could be proved by combining lower and upper bounds.

RELATED NOTIONS

If T is restricted to be a path, we refer to $(\{X_i, i \in I\}, T = (I, F))$ as a *path decomposition* and the best width as the *pathwidth* of G . The pathwidth of a tree can be arbitrarily large. One is referred to survey papers [2, 61] for a more thorough exposition of pathwidth.

A notion closely related to treewidth is the branchwidth of a graph, also introduced by Robertson and Seymour [62, 63].

Definition 1. A *branch decomposition* of a graph $G = (V, E)$ is a pair $(T = (I, F), \sigma)$, with T a ternary tree (a tree where every non-leaf node has degree 3) with $|E|$ leaves, and σ a bijection from E to the set of leaves of T .

The *order* of an edge $f \in F$ is the number of vertices $v \in V$, for which there exist adjacent edges $\{v, w\}, \{v, x\} \in E$, such that the path in T from $\sigma(v, w)$ to $\sigma(v, x)$ uses f .

The *width of branch decomposition* $(T = (I, F), \sigma)$, is the maximum order over all edges $f \in F$. The *branchwidth* of a graph G , $bw(G)$, is the minimum width over all branch decompositions of G .

The notions of branchwidth and treewidth are closely related to each other, as expressed in the following theorem.

Theorem 4 [62]. Let $G = (V, E)$ be a graph with $E \neq \emptyset$. Then $\max(\beta(G), 2) \leq \tau(G) + 1 \leq \max(\lfloor \frac{3}{2}\beta(G) \rfloor, 2)$.

One can easily convert a branch decomposition into a tree decomposition such that the respective widths fulfill these inequalities. As a result, algorithms computing a branchwidth upper bound (or exactly) also provide an upper bound on the treewidth of the graph.

Since branchwidth can be computed in polynomial time for planar graphs [64], this algorithm provides a $\frac{3}{2}$ -approximation for treewidth of planar graphs. Improved implementations of this algorithm can be found in Ref. 65. For general graphs, heuristics have been developed by Cook and Seymour [14, 63], Hicks [66], and Robertson and Seymour [67]. Further information on branchwidth can be found in Ref. 68.

This article provides a review of the existing and ongoing research that uses mathematical modeling and analysis to better understand and help improve triage decisions in the immediate aftermath of mass-casualty incidents (MCIs). An MCI is an event that results in a massive number of casualties with severe injuries that require medical attention immediately. Typical examples include plane crashes, earthquakes, and terrorist bombings. In the wake of an MCI, emergency response resources are overwhelmed by a sudden jump in demand, and medical resources need to be rationed in some way so as to minimize the number of deaths and permanent injuries. One part of this rationing process is the determination of priorities according to which patients will have access to these limited resources. We call this *triage*. In practice, the word *triage* is typically used to refer to the process of assessing the injury severity of patients, which automatically determines their priority levels. Here, we are using the word *triage* more broadly to refer to the decision of identifying the injury severity and determining priority levels of patients.

The word *triage* comes from the French word “trier,” which simply means “to sort.” The earliest accounts of triage date back to the Napoleonic Wars that took place in the first two decades of the nineteenth century. Although, the practice of triage started in the

military, it was eventually adopted in civilian life as well, especially after World War II. The whole idea behind triage is to efficiently use scarce resources, such as medical personnel, operating rooms, and ambulances by determining the order according to which patients will have access to these resources. For more on the history and practice of patient triage, see Iserson and Moskop [1].

In daily emergencies, resources are typically sufficient to keep up with the demand that comes from patients with severe injuries or life-threatening conditions and therefore, determining priorities is relatively simpler. Even though it is crucial that patients are correctly classified into triage classes, given the triage level of a patient, there is generally no question of which class should get a higher priority (see Argon and Ziya [2] for an analysis of errors in patient classification decisions). The most severe patients are treated first and the less severe patients who can wait are treated afterwards. This ensures that all patients have the maximum chance of survival that is possible given their injuries since typically, no critical patient experiences a significant treatment delay because of others who are given higher priorities. (It is important to note that average waiting times in emergency rooms can be very high but generally not for patients in life-threatening conditions, assuming they are correctly identified to be so.)

On the other hand, MCIs require a whole new approach to triage. MCIs are very different from daily emergencies because in MCIs, unlike in daily emergencies, an overwhelming number of casualties arrive almost simultaneously and their injuries tend to be much more severe. Because of severe resource restrictions, it is typically not possible to treat every patient in a timely manner. The objective of triage in such a mass event is to allocate scarce resources to do “the greatest good for the greatest number.”

According to Lerner *et al.* [3], which is a recent review paper on mass-casualty triage, there exist nine mass-casualty triage

systems, two of which are specific to pediatric patients. Most of these triage systems classify patients into 4–5 categories based on some physiological criteria such as breathing rate and pulse. As an example, consider one of the most widely adopted and used triage procedures in the United States, which is called *START* (Simple Triage and Rapid Treatment; e.g., Nocera and Garner [4]). According to *START*, patients are classified into one of four priority groups: immediate, delayed, minor, and deceased. Time-critical patients are generally either in the immediate or delayed category, immediate patients having priority over delayed patients. Patients in the minor category can wait longer, whereas patients in the deceased category have either died or have almost no chance of survival. Each patient is given a very quick evaluation as soon as possible and is tagged according to his/her *START* category with a colored marker. Then, each patient is given treatment in the order determined by his/her priority class (i.e., *START* category).

The main problem with *START* and most other mass-casualty triage systems is that patient categorization is made independently of the size of the disaster; that is, the number of patients waiting for care (or the available resources). Obviously, a patient's health condition does not change with the number of other casualties; however, from a system's optimization point of view, this information can be very useful to achieve the greatest good for the greatest number. For example, if the situation is so severe that it is only possible to save a fraction of the casualties at best with the given resources, then it may make more sense to redistribute the resources from the more time-critical with the most severe injuries toward the less time-critical patients who are more salvageable [5].

We are aware of two lines of research that use operations research (OR) tools for the analysis of the mass-casualty triage problem. The first approach [6,7] is based on a linear program that determines the best order for transporting patients from the scene to nearby hospitals. The second approach [8–10] models the problem as a stochastic scheduling problem and uses several

techniques (such as dynamic programming and heuristic methods) to provide insights and solutions to the mass-casualty triage problem. As we discuss later in the sections titled “A Linear Programming Approach to Mass-Casualty Triage” and “A Stochastic Scheduling Approach to Mass-Casualty Triage” in detail, the two approaches share some similarities but in essence the former is more of a medical research that employs an OR methodology (namely linear programming) and proposes a real-time solution method, whereas the latter is essentially an OR work that solves a general model from which insights into mass-casualty triage can be developed. Despite the differences between these two lines of research, main insights are similar. First, in order to maximize the number of survivors, mass-casualty triage systems should take into account the severity of the event; that is, the number of casualties and the capacity of the resources. Second, a “good” categorization of patients is essential for the success of the triage effort and such a categorization should be based on how the patients' health deteriorates, their service requirements, and survival probabilities.

We review the two OR approaches discussed above in the subsequent sections. Note that this review is exclusively for patient triage and prioritization decisions at pre-hospital and hospital levels in the aftermath of mass-casualty incidents. However, the insights that come out of the reviewed work may also carry over to other prioritization decisions that are commonly faced in such emergencies. For comprehensive reviews of the OR literature on emergency response systems, the interested reader is referred to Green and Kolesar [11] and Larson [12].

A LINEAR PROGRAMMING APPROACH TO MASS-CASUALTY TRIAGE

To our knowledge, within the emergency medicine literature, the only work that uses a mathematical approach for mass-casualty triage is by Sacco *et al.* [6,7]. In these two papers, Sacco and his coauthors formulate

the mass-casualty triage problem as a linear program and call their approach the Sacco Triage Method (STM). STM is mainly developed for primary triage in which the objective is to determine which patients will be transported first from the field to nearby hospitals in case of a mass-casualty incident. Under this method, the triage procedure begins with a brief physiological assessment of patients at the field. Based on this assessment, each patient is assigned a criticality score between 0 and S , where a smaller score indicates a more severe health condition. More specifically, STM uses the RPM (respiratory rate, pulse rate, and best motor response) scoring system [13]. For RPM, $S = 12$.

Once each patient is assigned a score, a central controller enters the available data (i.e., the number of patients in each criticality state denoted by the RPM score) into a computer that solves a linear program and determines the order according to which patients should be transported. The planning horizon is divided into T time periods enumerated as $1, 2, \dots, T$. (Although the formulation is general, the authors set the length of each period to be 30 min in their numerical analysis.) The capacity of service is defined in terms of the maximum number of casualties that can be served per period, which is denoted by R_n for period n . It is assumed that transportation times are deterministic and capacity in each period is known. The patients' health conditions are assumed to deteriorate deterministically while they wait for their turn for transportation. More specifically, knowing the initial RPM score of the patient right after triage is sufficient to know exactly what the condition of the patient would be at any point in time in the future. The health condition of the patient (measured in terms of the RPM score) at the time he/she was transported to the hospital affects his/her survival probability. The objective is to determine which patients should be transported in each period to maximize the expected number of survivors.

The problem is formulated as follows. Let $V_{s,n}$ denote the decision variable that denotes the number of casualties served in time period n whose RPM score is s at the time of triage, where $n = 1, 2, \dots, T$

and $s = 0, 1, \dots, S$. Let $P_{s,n}$ be the survival probability of a patient with an initial RPM value of s when transported in period n and Q_s be the number of casualties whose initial RPM score is s .

Below is the linear programming formulation that the STM is based on:

$$\text{Maximize } \sum_{s=0}^S \sum_{n=0}^T P_{s,n} V_{s,n} \quad (1)$$

subject to

$$\begin{aligned} \sum_{s=0}^S V_{s,n} &\leq R_n, \quad \text{for } n = 1, 2, \dots, T \\ \sum_{n=0}^T V_{s,n} &= Q_s, \quad \text{for } s = 0, 1, \dots, S \\ V_{s,n} &\geq 0, \quad \text{for } s = 0, 1, \dots, S \text{ and } \\ &n = 1, 2, \dots, T. \end{aligned}$$

The performance of the solution of the above linear program has been numerically tested for two different types of injuries. In Ref. 6, the focus is on blunt trauma victims whereas Ref. 7 studies victims with penetrating injuries. In both studies, the survival probabilities are estimated using a logistic regression. More specifically, the survival probability of a patient with health score s is modeled by

$$P_s = \frac{1}{1 + e^{-(w_0 + w_1 s)}}, \quad (2)$$

where the logistic regression coefficients w_0 and w_1 are estimated from the data collected from hospitals that participated in the Pennsylvania trauma outcome study. The pattern of deterioration of patients' health conditions (indicated by their RPM scores) is estimated by the Delphi technique used by Linstone and Turoff [14]. Following the Delphi method, a panel of experts on trauma care provided estimates of scene RPM value changes in increments of 30 min during a 6-h period assuming minimal medical interventions during that period. After two iterations of taking such estimates, the median changes in RPM values for successive periods for each initial RPM value were obtained. As

Table 1. RPM Score Estimates as Function of 30-min Time Intervals Presented in Table 3 of Ref. 7

Initial RPM	Time Interval (n)											
	1	2	3	4	5	6	7	8	9	10	11	12
12	12	12	11	11	10	10	9	9	9	8	8	8
11	11	11	10	10	9	8	7	7	7	6	5	5
10	10	9	9	8	8	7	6	5	5	5	4	4
9	9	8	8	7	5	4	3	1	0	0	0	0
8	7	6	4	3	3	2	2	0	0	0	0	0
7	6	5	3	1	0	0	0	0	0	0	0	0
6	4	3	2	1	0	0	0	0	0	0	0	0
5	3	2	0	0	0	0	0	0	0	0	0	0
4	2	0	0	0	0	0	0	0	0	0	0	0
3	1	0	0	0	0	0	0	0	0	0	0	0
2	0	0	0	0	0	0	0	0	0	0	0	0
1	0	0	0	0	0	0	0	0	0	0	0	0
0	0	0	0	0	0	0	0	0	0	0	0	0

an example, see the Delphi estimates of RPM values for penetrating injuries from Ref. 7 in Table 1. These RPM estimates, as a function of time, are then used in Equation (2) to obtain $P_{s,n,s}$, which are later plugged into the linear program given in Equation (1).

In both, Refs 6 and 7, the performances of the STM and START triage method are compared by means of a numerical study. This numerical study is performed under the same assumptions that the model was built upon, that is the service times are deterministic, and success probabilities are known functions of time. Hence, not surprisingly, the STM method, which is the optimal solution under the given assumptions, yields the best performance. However, the numerical study is still useful because it provides insights on the magnitude of improvement provided by STM over START and also on types of events where using STM in place of START has a potential to make the biggest impact. In particular, the authors observe that START performs close to STM when the patients' conditions are not very critical. However, for events where the resources are overwhelmed with a large number of victims having severe injuries, STM performs significantly better than START. It is especially important to note that when resources are severely overwhelmed, worst-first triage policy (i.e., the policy that serves the patients with the smallest RPM value first) performs very badly.

As the resources become more scarce, STM tends to give priority to patients in less critical conditions but who have higher chances of survival, thereby achieving an improvement in the expected number of lives saved.

The main observation in Refs 6 and 7 is that most of the current mass-casualty triage methods such as START do not take into account the resource limitations. Furthermore, the triage categories for these methods are very crude (only 4–5 categories) meaning that among patients that are classified into the same triage class, there could be a huge variation in terms of survival probabilities. One could significantly improve the expected number of survivors by implementing a triage system that divides patients into categories based on better predictions of their survival probabilities and then applying a mathematical approach that considers resource limitations to determine the order of service for patients in different classes.

A STOCHASTIC SCHEDULING APPROACH TO MASS-CASUALTY TRIAGE

One way of modeling patient triage in MCIs is to view it as a standard job scheduling problem in a clearing system where there is a finite number of jobs all available for service at time zero but can possibly renege before their turn for service. Here, jobs are

the patients with various criticality levels and renegeing corresponds to the death of a patient (or reaching a stage where survival is almost impossible even with the appropriate medical intervention). To our knowledge, there are only three papers in the OR literature that studied this model: Refs 8, 9, and 10. Argon *et al.* [9], in particular, report several insights drawn from the analysis of this clearing model for mass-casualty triage. In this section, we will discuss the main results from these three papers and also provide insights on the mass-casualty triage problem.

Patient Triage as a Job Scheduling Problem

Suppose that in the immediate aftermath of an MCI, there is a finite number of patients at various criticality levels that are in need of access to a scarce resource, which is crucial for the patients' survival. We call this scarce resource the "server." Depending on the circumstances, the server may represent an emergency vehicle that will transport patients to nearby hospitals, a doctor or a nurse in the field, or an operating room at the hospital. Suppose that patients are instantaneously put into one of M different categories (e.g., based on their injury characteristics) and there are m_i patients of type $i \in \{1, 2, \dots, M\}$ at time zero. Each patient type is characterized by its lifetime and service time distributions, denoted by $F_i(\cdot)$ and $G_i(\cdot)$ for type i patients, respectively. Here, the lifetime of an injured patient represents the time he/she can tolerate waiting in the absence of any medical intervention. In general, the lifetime distribution would heavily depend on the injury characteristics. For example, patients with intracerebral hemorrhage are expected to have a shorter lifetime than patients with crush injuries to the leg. Note that since the model allows the service time distribution to depend on patient types, the insights that come out are relevant not only to pre-hospital triage but also to hospital-level triage where the service time is likely depend on the injury types.

The objective for this scheduling problem is to dynamically determine the order that patients are taken into service so as to maximize the number of survivors under

the assumption that patients who are admitted before their death survive with certainty. This problem can be formulated as a semi-Markov decision process where the state space at the time the server is ready to choose the next patient can be described by an $(M + 1)$ -dimensional vector $(t, x_1, x_2, \dots, x_M)$, where t denotes the time passed since the incident took place, and x_i is the number of type i patients who are still alive and in need of attention.

Analytical Results

For ease of presentation, we adapt the following terminology:

Definition 1. If the lifetimes of type i patients are smaller than those of type j patients in the hazard rate sense (i.e., $F_i \leq_{hr} F_j$), then patients of type i are said to be more *time-critical* than patients of type j , for $i, j \in \{1, 2, \dots, M\}$ and $i \neq j$. (For definitions of stochastic orders used in this article, see Ref. 15.)

With this definition, higher time-criticality indicates higher urgency to serve the patient at any point in time as hazard rate ordering implies that patients who are more time-critical have shorter remaining lifetimes in the usual stochastic sense at any point in time. Nevertheless, time-criticality by itself does not determine priorities. If it takes a long time to serve a highly time-critical patient, it might be preferable to serve those patients who are not as critical but can be served in a shorter time. However, if it does take a shorter time to serve time-critical patients in some stochastic sense, it might be reasonable to give priority to them. The following theorem formalizes this result. Note that, $G_i \leq_{lr} G_j$ means that G_i is smaller than or equal to G_j in likelihood ratio ordering, which implies $G_i \leq_{hr} G_j$.

Theorem 1. Suppose that $F_1 \leq_{hr} F_2 \leq_{hr} \dots \leq_{hr} F_M$ and $G_1 \leq_{lr} G_2 \leq_{lr} \dots \leq_{lr} G_M$. Then, the policy that prioritizes one of the patients of the type with the smallest index maximizes the total number of survivors in the usual stochastic sense.

Theorem 1, which is proved in Ref. 9, gives a complete characterization of the optimal policy when lifetimes and service times are *agreeably ordered* with respect to the hazard rate and likelihood ratio orders, respectively. Under such a condition, the optimal policy turns out to be a simple, state-independent policy. To be more specific, the optimal priority ordering of the patients is the same regardless of time and the number of patients at various criticality levels. However, this simplicity comes with the expense of a strong condition that essentially requires that it takes less time to serve more critical patients, but this is not very likely to hold in practice. In the absence of such a condition, however, the analysis becomes significantly more challenging even under certain distributional assumptions for lifetimes and service times. We next describe some results that characterize the optimal policy under such distributional assumptions.

Suppose that there are only two types of patients. For patient type $i \in \{1, 2\}$, lifetimes and service times are both exponentially distributed with respective rates r_i and μ_i . Without loss of generality, assume that $r_1 > r_2$ so that type 1 patients are more time-critical than type 2 patients. If $\mu_1 \geq \mu_2$, then the agreeability condition of Theorem 1 holds and thus, the optimal policy is to give priority to type 1 patients at all times regardless of the number of patients at various criticality levels that are still in need of service. Instead, we assume that $\mu_1 < \mu_2$ under which the

optimal policy is not known. In this case, the optimal policy is possibly state-dependent and numerical analysis suggests that in most cases it can be characterized by a threshold curve over the state space, which separates the region where type 1 patients should be served from that where type 2 patients should be served. This structure is shown in Fig. 1. Note that because of the memoryless property, the optimal policy does not depend on time and is purely described as a function of the number of patients at the two criticality levels (x_1 and x_2).

Figure 1 suggests that if the number of patients is large, then giving priority to less time-critical patients who require shorter service (i.e., type 2 patients) becomes a better strategy. This policy is quite different from the common practice of triage for daily emergencies where priority is always given to time-critical patients. In daily emergencies, resources are usually not overwhelmed by very critical patients who have life-threatening conditions and therefore the basic principle is to give them the highest priority. However, in the aftermath of mass-casualty events, available resources may not be sufficient to provide the best possible care to each patient, which may require a switch from the regular daily operating mode. As we observe from Fig. 1, when the number of patients overwhelms the resources significantly, it is optimal to give priority to less critical patients if they keep the resource occupied for a shorter period of time. However, as

Figure 1. A typical structure for the optimal policy when $\mu_1 < \mu_2$ and $r_1 > r_2$, that is, when time-critical patients have longer service times [9].

soon as the number of patients drops, the priority policy switches back to the daily mode and priority is given to the most time-critical patients even if it takes longer to treat them.

For the Markovian model with two types of patients, Argon *et al.* [9] formulated a dynamic program and obtained a number of analytical results that provide further insights into the optimal policy in the absence of the agreeability condition of Theorem 1. We present two of these results:

Proposition 1.

- (i) If $\mu_1 < \mu_2 \leq r_2$ and $\mu_1 \leq r_1$, then for every x_1 , the optimal policy has a threshold, $t(x_1)$ (which may be infinite), such that for all $x_2 \geq t(x_1)$, it is optimal to serve a type 2 patient.
- (ii) If $r_1 \leq \mu_1 < \mu_2$ and $r_2 \leq \mu_2$, then for every $x_1 \geq 1$, the optimal policy has a threshold, $\tilde{t}(x_1)$ such that for all $x_2 \leq \tilde{t}(x_1)$, it is optimal to serve a type 1 patient, where

$$\tilde{t}(x_1) = \frac{r_1\mu_2 - r_2\mu_1}{r_2(\mu_2 - \mu_1)} - \frac{x_1r_1}{r_2}.$$

Proposition 1 formalizes the threshold structure that is observed in Fig. 1 under certain conditions on lifetimes and service times. More specifically, Proposition 1 implies that when the number of patients is large, then serving patients with shorter service times is optimal if the deaths occur faster than service (i.e., $r_i \geq \mu_i$ for $i = 1, 2$).

Proposition 2. If $\mu_1 < \mu_2 \leq r_2$, $\mu_1 \leq r_1$, and $r_1\mu_1 \leq r_2\mu_2$, then it is optimal to serve a type 2 patient in any state (x_1, x_2) such that $x_2 \geq 1$.

Proposition 2 provides a set of conditions under which the optimal policy is a state-independent policy that always calls for serving patients that are faster to serve. These conditions imply that the patients with faster service should be prioritized if the deaths occur at a faster rate than service and the conditions of the faster-to-serve patients are

sufficiently critical (if not as critical as the slower-to-serve patients).

Argon *et al.* [9] conjecture that Proposition 2 holds under less restrictive conditions based on extensive numerical experimentation. More specifically, it is conjectured that the $r\mu$ rule, which gives the priority to the type with the highest $r_i\mu_i$ score, is optimal if it also agrees with the shortest expected processing time (SEPT) rule.

Besides the above conjecture, the $r\mu$ rule has also been supported by two analytical results. A simple argument shows that if the optimal policy for the Markovian system with two types of patients is a state-independent policy, then it must agree with the $r\mu$ rule [9]. Furthermore, Glazebrook *et al.* [8] prove the “asymptotic” optimality of the $r\mu$ rule. To be more specific, let K , v_1 , and v_2 be defined so that $r_i = Kv_i$.

Theorem 2. Suppose that $r_1\mu_1 \leq r_2\mu_2$. Then the expected number of survivors under the policy that always gives priority to type 2 patients converges to the expected number of survivors under an optimal policy as K approaches to zero. In other words, the $r\mu$ policy is asymptotically optimal as the expected lifetimes for all patients go to infinity.

Theorem 2 implies that if the patients do not have serious injuries so that their lifetimes are sufficiently large, then regardless of the number of patients in the system, the priority should be given to the patient type with the largest $r\mu$ value.

Heuristic Methods and their Performance

Since it is difficult to fully characterize the optimal policy in the absence of the agreeability condition of Theorem 1 or the conditions of Proposition 2, it is of interest to develop heuristic methods. In the literature, four methods have been proposed: the $r\mu$ policy, two myopic policies (triangular and rectangular heuristics), and the PI- $r\mu$ policy.

The $r\mu$ Rule (by Glazebrook et al. [8]). As we discussed earlier, this policy is a state-independent policy according to

which the priority score of type i is $r_i\mu_i$ and the type with the higher score has a higher priority.

Myopic Policies (by Argon et al. [9]).

These policies are based on the idea of maximizing short-term (myopic) gains. More specifically, the *triangular heuristic* (one of the two myopic policies) maximizes the expected immediate “reward.” The reason that the policy is called *triangular heuristic* is that under this heuristic in the two dimensional representation of the state space (as in Fig. 1), states in which more time-critical patients are given priority forms a triangle. More specifically, the dark region in Fig. 1 is approximated by a triangle under this policy. The *rectangular heuristic* is obtained from the *triangular heuristic* by simply expanding the triangular region to a rectangle so as to obtain a simpler policy that can be described by only two threshold values that determine the lengths of the sides of the rectangle.

The PI- $r\mu$ Policy (Li and Glazebrook [10]).

This policy is obtained by applying a single step of the standard policy improvement algorithm for Markov decision processes on the $r\mu$ policy and using a fluid approximation for the value function of the $r\mu$ policy.

Among these policies, the $r\mu$ policy is the only one that is state-independent. The numerical study by Argon et al. [9] shows that this policy performs very well when the lifetimes are long, which is not surprising given Theorem 2. However, it has a poor performance when lifetimes are short. In such a scenario, the myopic policies (triangular and rectangular heuristics) perform much better than the $r\mu$ policy especially when there is a large number of casualties. On the other hand, the most recently proposed PI- $r\mu$ policy is not as simple as the other policies, but appears to perform exceptionally well across all scenarios.

Other Relevant Literature

In a working paper, Uzun et al. [16] analyze a more general version of the model described in the section titled “Patient Triage as a Job Scheduling Problem” using a model where customers possibly belong to more than two types, there are multiple servers, and each service brings a reward that depends on the patient’s type. In the context of the patient triage problem, the reward of service could be thought of as the probability of success from service, in which case the objective of the problem would be the maximization of the expected number of survivors. One could also set the reward of service to be the quality-adjusted life years (QALY) for the patient who goes through that service process. This allows taking into consideration factors such as age and pre-existing conditions as well as the injuries caused by the emergency event when making prioritization decisions. In Uzun et al. [16], the authors generalize Theorem 1, and give partial characterization of the optimal policy under certain conditions. They also numerically test a number of easy-to-implement near-optimal policies and show that they perform well.

There are also several articles in the traditional job scheduling literature on clearing systems that are closely related. However, none of the models studied in this literature suit the patient triage problem well. Among them, Refs 17, 18 and 19 appear to be the most relevant. The objective in these papers is to minimize the (weighted) number of tardy jobs (i.e., jobs not completed by their due date). Pinedo [19] and Boxma and Forst [17] consider only *list scheduling policies*, according to which the schedule is fixed at time zero and cannot be changed later on. This does not quite fit with the patient triage problem since under list scheduling policies, tardy jobs also get served. Emmons and Pinedo [18] study both, list scheduling and dynamic policies. They provide a number of cases for which optimal dynamic policies or list scheduling policies can be identified. They find that if the processing times are independent and identically distributed exponential random variables, and the due dates (e.g., lifetimes) are independent and can be ordered according to their failure rates, the optimal *preemptive*

dynamic policy is to process the jobs in the increasing order of their failure rates.

Finally, a number of articles from the stochastic scheduling literature consider systems with stationary arrival processes under the objective of minimizing weighted average number of tardy jobs with the assumption that jobs come from a single type. The main application domain for this scheduling problem is communication systems. Among these articles, Refs 20 and 21 show that when the due dates are announced at the time of arrivals, under certain conditions, one form of the “shortest-time-to-extinction” policy is optimal. Bhattacharya and Ephremides [22] and Zhao *et al.* [23] consider models where the due date is not announced but the service provider knows its probability distribution. In particular, Bhattacharya and Ephremides [22] find that if jobs have independent and identically distributed lifetimes, service times, and interarrival times, and lifetime distribution has a non-decreasing failure rate, the “earliest-arrival” policy is optimal.

CONCLUSIONS

In this article, we reviewed the growing literature on mathematical modeling and analysis of patient triage and prioritization decisions in the aftermath of mass-casualty events. In particular, we discussed two lines of research where one formulates the decision problem as a linear program and proposes that this problem be solved in real-time, whereas the other uses a stochastic job scheduling formulation in order to generate insights that can be later used in developing practical and simple policies. Despite their differences on main objectives and modeling approaches, both lines of work demonstrated the potential benefits of dynamic adaptive triage policies that take into account the number of casualties and the availabilities of resources to maximize the number of people saved.

Mass-casualty triage and patient prioritization is a complex but a very important problem that has not drawn much attention from the OR community. Considering the

typically chaotic environment that follows a mass-casualty event and the fact that each mass-casualty event typically tends to have its own unique unexpected challenges, it is difficult to imagine a sophisticated decision support tool that can be used in real-time. However, insights that come out of the mathematical models can help in the development of effective and practical policies.

More research is needed across various dimensions. In particular, injuries that could result from specific emergency events should be researched in depth to provide reliable input for the mathematical models. There is also a need for new innovative formulations that lead to fresh insights on the problem. Furthermore, extensive realistic simulation models should be developed in order to test the general validity of the insights that come out of stylized models. Operations researchers can help in developing an understanding of the potential outcomes of different kinds of priority policies, which can be very helpful to the medical community who ultimately have the responsibility of adopting policies that are practical, effective, and ethical. A successful outcome will ultimately require a significant effort from both, medical and operations research communities.

TRUST

ROBERT GODFREY
Madison, Wisconsin

The nature of trust and its role across a wide variety of social relationships—from personal friendships [1], to relations between professionals, clients, and business dealings [2], interactions within and between organizations [3], and even relations between citizens and their government [4]—has received both a wide and extensive review in the literature, across many branches of knowledge. Varied disciplines, such as psychology, social psychology, sociology, political science, economics, and mass communication, have each approached this subject in sometimes markedly different ways (Rousseau *et al.* [5] offer an extensive review). However, in general, they remain interested in learning how trust affects the workings of a relationship, how it enables cooperation, and how it is achieved, lost, and regained. Many types of research questions are posed, including: What are the sources of trust? What role does trust play in supporting institutions such as the market economy or representative government? Is trust between friends analogous to the “trust” a government might be said to inspire in its citizens? Is more trust necessarily a good thing, and when is it unwarranted, naive, and harmful? How can we best measure trust, and what kinds of evidence do we need to discriminate between rival theories?

For the purposes of this article, however, our focus on trust will largely be confined to those elements of research on the subject that can have applicability within the domains of risk, risk management, risk perception, and risk communication. We will begin with a review of the efforts to define the concept of trust, one with a long and complex history. Next, we will examine the important work that has been done exploring trust in the managers of risk. We will turn to source believability and the effects of involvement with an issue. The reader’s attention will

be then be directed to a thorough review of the importance of cognitive simplicity seeking and the role that values play in this process. We complete our survey with a short overview of the importance of assessing benefits in trust analysis.

THE IMPORTANCE OF TRUST

Trust is obviously a valued currency in use throughout society. It is a complex phenomenon to conceptualize, operationalize, and study. It also varies in meaning and context. The role of trust has been shown to be of critical importance in the literature on risk perception, risk communication, and risk analysis in general [6]. This observation is no better illustrated than by the oft-noted public concern with environmental effects stemming from the application of technology, which in turn has been paralleled by a decline in trust of those responsible for developing safe technologies and the governmental regulatory agencies meant to monitor their development [7]. At the same time, some research has shown that those who are willing to place their trust in an institution or group appear to find the risk estimates of those bodies more credible and their hazard policies more acceptable [8–10]. Indeed, as Slovic [11] and others have asserted, trust may be more fundamental to one’s ability to both understand and weigh certain potential risks than any strategy of risk communication. And as research by Mutz [12] has suggested, “levels of social trust are malleable... [and] can be altered by what [individuals] see, hear, and read” (p. 409). Consequently, discussions related to the most effective techniques for conveying information to the public about hazards and risks have quite often focused on questions of trust.

DEFINING TRUST

Perhaps one of the more notable features about the study of trust is the many seem-

ingly disparate definitions, descriptions, and characterizations that have been applied to the concept. There are a number of similar, but nonetheless multifaceted, themes and definitions.

From the field of psychology, one of the oft-noted studies of Rotter [13] defined trust “as an expectancy held by an individual or a group that the word, promise, verbal or written statement of another individual or group can be relied upon” (p. 651), while noting that one can learn to distrust large groups of people without personal experience validating such distrust. A factor analysis of the trust scale developed by Rotter [13] was found by Rotenberg [14] to yield three reliable factors: (i) political cynicism, which is skepticism about politicians and political bodies; (ii) interpersonal exploitation, which is a cautious orientation that corresponds to the perception of others as exploitive; (iii) belief in the dependability of people, which is the belief in the consistency between what others say and do. Chun and Campbell [15] identified a fourth factor that they labeled “societal hypocrisy,” the failure of social members to live up to commonly held expectations of behavior. Parks and Hulbert [16] defined trust as “the belief that others will not exploit one’s goodwill” (p. 719). They saw a firm connection between trust and cooperation. Yamagishi [17] did as well. The two most important factors observed in a factor analysis were the beliefs that people are basically honest and that trusting others is risky; both predicted subject’s cooperation level. Coleman [18] defined it in arguably more general terms as a voluntary expectation on the part of the trustor that he or she will receive a benefit from participating in an interaction with another trustee and not be hurt by it. Renn and Levine [19] characterized trust as “the generalized expectancy that a message received is true and reliable and the communicator demonstrates competence and honesty by conveying accurate, objective, and complete information” (p. 181). Rempel and Holmes [20] expressed it as, “the degree of confidence you feel when you think about a relationship” (p. 28) and Zucker [21] “as a set of expectations shared by all those involved in an exchange” (p. 54). Lewis and

Weigert [22] contended that, “members of that system act according to and are secure in the expected futures constituted by the presence of each other or their symbolic representations” (p. 965). While Koller [23] reasoned that trust is “a person’s expectations that an interaction partner is able and willing to behave promotively toward the person even when the interaction partner is free to choose among alternative behaviors that could lead to negative consequences for the person” (p. 266). Luhmann [24] defined it as, “an attitude which allows for risk taking decisions” (p. 95), and Fukuyama [25] has examined it within norms such as professional competency: for example, the audience’s belief in the professionalism of journalistic practice as the foundation for trust in journalism. Trust, is “the bedrock perception upon which society is possible” [26, p. 229].

The disciplines of political science and political communication reveal other definitions of trust. Lambert *et al.* [27], like many researchers, have produced an index of questionnaire items meant to measure trust as part of a larger study. Their questions concerning political trust dealt with dishonesty, fiduciary incompetence, and the ability to trust people in government to do what is right. Parker [28] attempted to measure a constituent trust index. Distrusting responses referred to the incumbent’s pursuit of self-interest, lack of integrity (principles), untrustworthiness, dishonesty, or lack of independence (controlled by political bosses or parties); constituent trust is reflected in responses that are the opposite of these (e.g., honesty, trustworthiness, integrity). It is interesting to note that in this study, Parker [28] found that 78% of the respondents gave more trusting evaluations of their congressperson than distrusting ones, a conclusion similar to other studies. This directly contrasts with other findings that show a strong distrust for the government in general. Howell and Fagan [29] composed an index related to questions of local trust. Again, fiduciary competence, the ability to trust people in government to do what is right, honesty, and equal representation of interests were

the items used for this purpose. Wald and Lupfer [30] used items related to ability to trust people in government to do what is right, equal representation of interests, general competence, fiduciary competence, and honesty.

Barber [31] concluded that trust has its roots in certain expectations people have of one another. There are three kinds of expectations:

“1) the expectation of the persistence and fulfillment of the natural and moral orders (e.g., the persistence of everyday routines we assume to be inevitable); 2) the expectation of technically competent role performance by the trusted individuals; 3) the expectation that these individuals will carry out their fiduciary obligations” (p. 9).

Barber [31] contended that the American political system depends on these three types of expectations, ones that are signified by the term “trust.” He maintained that since trust is an important component of power, when it is eroded, or was never present in the first place, we have distrust. Distrust is much more than the opposite of trust; it is also its equivalent. In other words, those on the lower end of the power distribution have a choice of whether to trust or not. Effective distrust leads to an equalization of power, and, consequently, the actions of the (formerly) trusted person or group are effectively monitored for competence and fiduciary responsibility. Barber [31] concluded, “trust is never enough for effective social control because the differential power of various groups in society has consequences that cannot be satisfactorily managed by trust alone” (p. 65).

Slovic [11] has noted that, generally, trust is fragile. It is slow to develop and, “can be destroyed in an instant—by a single mishap or mistake. Thus, once trust is lost, it may take a long time to rebuild it to its former state” (p. 677). For example, Rothbart and Park [32] found that, when people were asked to rate various descriptive traits of people, unfavorable traits were judged to be easier to acquire and harder to lose, taking more effort to disconfirm than a positive trait. Trustworthiness required a relatively

large number of confirming acts to establish the trait and a relatively small number of instances to disconfirm it. Slovic [11] observed that the ease with which trust is destroyed and the difficulty in creating it are due to a couple of factors. Negative (trust-destroying) events are more visible or noticeable than positive (trust-building) events. Negative (trust-destroying) events also carry much greater weight. Sources of bad (trust-destroying) news tend to be seen as more credible than sources of good news. Distrust, once initiated, tends to reinforce and perpetuate itself. This, according to Slovic, is because there is a tendency to inhibit the kinds of personal contacts and experiences that are necessary to overcome distrust. See also the notion of “recreancy” explored by Freudenburg [33,34]. At the same time, initial trust or distrust tends to color our interpretation of events—reinforcing our prior beliefs. Fischhoff [35] cited the example of the accident at Three Mile Island. For the antinuclear activists, Fischhoff suggested, the incident would have strengthened their resolve to ask only “how likely is such an accident, given a fundamentally unsafe technology?” while at the same time leading the pronuclear activists to ask only “how likely is the containment of such an incident, given a fundamentally safe technology?” (p. 300).

Standard definitions of trust from different literature share some general themes. Kasperperson *et al.* [36] summarized the most important attributes of trust to include the following:

“1) *Expectations about others and orientations toward the future.* Trust provides people with the ability to interact and cooperate without the full knowledge about others and future uncertainties. 2) *A notion of chance or risk taking.* The concept of trust instills confidence that others will act voluntarily in a manner that is beneficial. 3) *Subjective perceptions about others and situations.* These include perceptions of the intentions and attributes of others (e.g., commitment, competence, consistency, integrity, honesty), their motivations, qualities of the situation (e.g., the availability and accuracy of information), risks, and uncertainties” (p. 162).

The most basic of assumptions is that people are unlikely to attend to information, much less change their behavior or attitudes, if they do not trust the sources of risk information. Until recently, however, surprisingly little research has been initiated in this particular area of risk communication. Trust has traditionally been regarded as critical for social interaction and even for the survival of society [37,38]. It has also been found to be important during all aspects of childhood development [14]. Given that it holds such an important place in our day-to-day lives, it is surprising, as Stebbins [39] has noted, that “trust is an idea that is overused and understudied, clumsily defined and hotly contested, ideologically valued and concretely abused. While there are commentaries about and studies of trust in such varied and particular areas of life as research, family, and politics, generalized, comparative analyses of it is rare” (p. 475). Kasperson *et al.* [10] further contended that “trust is a concept widely identified as important to social interactions, but rarely well defined or characterized” (p. 164). Kramer and Tyler [40] have summarized in their literature review as many as 16 different definitions of the word trust. As Johnson [41] has observed, despite the findings from several studies pointing to the importance of trust as a factor in people’s responses to potentially risky situations, “we know very little about what drives trust judgments. This ignorance is due both to the recency of such research and use of vague (and sometimes the absence of appropriate) measures” [41, p. 348].

TRUST IN THE MANAGERS OF RISKS

Two research traditions have dominated this area of research into the overseers of risks. One includes the literature of persuasion/mass communication studies and will be discussed shortly. The second, the study of risk and science communication, has placed an especially important focus on the degree to which people trust the abilities of science, business, and government to manage danger (sometimes referred to as either fiduciary responsibility or care), and has been shown

to be one of the best predictors of the level of concern about various risks tied to the managers of those risks [7]. Frewer *et al.* [42] have noted the importance of distinguishing between the concepts of “social trust,” with its origins in sociopolitical analysis, and the concept of “source credibility” which is derived from empirical research in applied social psychology. The increasing social and technical complexity of modern living makes for more elevated probabilities that one’s expected length and quality of life are more threatened by incompetency, or even negligence, on the part of entrusted, responsible individuals and organizations, in the performance of their duties. Consequently, this division of labor in a complex society makes one more vulnerable to other’s failures. Institutional legitimacy, therefore, becomes an important variable.

Some have reasoned that social trust is the process by which individuals assign to other persons, groups, agencies, and institutions the responsibility to work on certain tasks [43]. Freudenburg [33,34] has contended that the degree to which people trust the abilities of science, business, and government to manage danger is the most important predictor of perceived risk. Some have argued that conflicts related to risk management are not due to easily dismissed factors such as public ignorance or irrationality, but instead are linked to the ongoing technological advances and social changes that have systematically destroyed trust in the sources of both control and communication of risk [44]. Viewing trust through a lens of a largely impersonal and compartmentalized technocracy-driven society would suggest less worry about technical issues related to differences in risk probabilities, and, instead, apprehension would lie with how risk decisions are made. Several similarly themed questions could arise: Are risk assessment decisions and the resultant risk management policies derived from those conclusions made fairly? Whose interests are ultimately served by the decision process? Why is one conclusion more valid than another? And, which authority is the ultimate arbitrator in the process?

As both Luhmann [24] and Earle and Cvetkovich [45] have noted, some people

make a judgment about trust and they determine that the outcome of actually being wrong is worth the risk. Others may be helped to assume this risk if they were to believe that they have the means to hold the trusted individual accountable, even if they were to learn later that trust was wrongly placed. This accountability for some may substitute for trust or, in the reverse, serve as a signal of distrust.

The concerns of the arbiters in these risk management systems (e.g., scientists, governmental regulators, etc.) are obviously quite different. For the many “experts” in positions of assessing, managing, or developing policy related to risks, there is a hope that the public will, with sufficient time and increased knowledge, view the risk in the same light as themselves. The concept of a knowledge deficit to be overcome with the help of the expert-as-information-provider, is a common paradigm. Concurrently, the very same expert can also be seen as a decision influencer, perhaps even a decision maker, by some. The noted breakdown in the process of placing trust in the knowledge of the expert has been tied to a crumbling in trust of what is assumed to be scientific rationality. An acknowledgement of that breakdown has even been sometimes used to enhance the credibility of decisions [43]. Not only is the expertise of scientists a factor, but as Fessenden-Raden *et al.* [46] found, for example, the level of trust people have in local political institutions and officials determines “the level of trust they place in the information local officials provide about a risk” (p. 96). They also reported that when state and federal agencies were suspected or even disliked, the risk information those officials provided was generally seen as less “true” than that from other sources (see also White and Eiser [47]).

As Petts [48] has observed, there are many frustrations in store when the scientific view is to be adapted to societal conditions. Petts suggested some likely outcomes: the “public are not interested; people have their own agenda and will not listen to ‘objective science’; involving activists and special interest groups will be detrimental to the education

process [of the experts]; that people inaccurately perceive risks; the scientific complexities underlying current techno-scientific debates make them difficult to discuss; and that the public will always go for the zero-risk option” (p. 359). The portrayal of scientific debates themselves are also fraught with problems in risk reporting. Frequently, stories are characterized by ambiguity and scientific debate, due in large part to the conventions developed for political reporting, utilizing conflicting sources in the debate to express the opposing spectrum of differences, while offering little interpretation of either the validity or the accuracy of the information. Consequently, this leaves consumers of risk reporting often in an uncertain situation; they may be unable to arrive at a decision regarding the veracity of the claims and counterclaims due to this lack of necessary information [49]. Along with these conditions, the intervening factor of trust can only further complicate the science communication process.

BELIEVABILITY OF SOURCES OF A RISK MESSAGE

Apart from the many hindrances that the scientific view faces in conveying information about risks to the public, the credibility of expert sources has also remained a critical area of concern for communication scholars in the literature of persuasion/mass communication studies. Understanding an individual’s perception of the credibility of the source of a risk message has been found to be an essential factor in identifying how individuals receive, process, and react to the plethora of risk messages that are received each day from various information sources [50].

Seminal work by Hovland and Weiss [51] and Hovland *et al.* [52] provided some of the early nuanced studies of source credibility and suggested it was composed of two major components—expertise and trustworthiness. Similarly, Eagly *et al.* [53] framed trustworthiness and expertise in terms of two types of expected bias on the part of the expert. Trustworthiness was transposed to a truthfulness characteristic

and termed a *reporting bias*, which corresponded to how willing a source would be to be truthful about a relevant issue. The degree of knowledge a source has about the issue was equated roughly with expertise. This was termed a *knowledge bias*—the knowledge a target audience attributes to a source. Consequently, trust will be reduced if the source is seen as having a high degree of reporting bias and/or an insufficiently informed knowledge about a particular hazard [54–57]. Hunt *et al.* [58] have noted that, while reporting bias seems to be more important than expertise, having these elements of trust present in “appropriate proportions” is more important for risk communication than simply a high trust rating alone; see also Frewer and Miles [59].

However, a rigid definition of credibility has not remained a research constant. Hovland and Weiss [51] have suggested, for example, that expertise is a less effective persuasive technique than is trustworthiness overall; see also McGinnies and Ward [60]. Issues concerning technological risk also suggest that trustworthiness is a more valued trait [61]. Gunther [62] observed that the relationship the receiver has to the content of a message will have an effect on the perception of the source’s credibility. Frewer *et al.* [63] observed that the relationship between trust and message content is a complex one. The variables in their study included both the level of perceived risk and the level of persuasiveness. If the information presented in a message was low in persuasiveness, greatest trust was observed when it was high in both personal relevance and attributed to the government, or low in personal relevance and attributed to a consumer organization. Some work by Johnson *et al.* [64] and Slater and Rouner [65] indicated that both the plausibility and quality of a message may matter more to assessments of source credibility, and to subsequent attitude change, than a source’s expertise and trustworthiness. Hamilton [66] has also described, for example, how ratings of source expertise and trustworthiness increase as argument quality increases. These different research results over the past few decades suggest that source credibility could be seen

as a relational concept and not as a fixed entity; see also Walls *et al.* [67]. However, it is important to acknowledge that contextual messages have had quite limited usage in studies of trust. A typical example can be found in [68]. An extensive 43-item trust index was employed to measure what was termed *general trust*, without reference to a context. The study listed specific, potential risks or hazards (e.g., “nuclear power”) without specifying what the actual risk was for the person completing the survey. This accounted for only a small fraction of the variance of perceived risk. An improved result was obtained when “specific trust ratings” were employed, a questionnaire asking for ratings of trust in the pertinent authorities for each of 22 hazards. These ratings of trust in specific actors tied to specific risks/benefits (e.g., university scientists, pharmaceutical companies) are a common noncontextual measurement of trust [69, p. 198].

Several other issues endemic to this line of research, typified by Sjöberg [68], have been noted by McComas and Trumbo [70]—the lack of attention to explication in past source credibility research, or indeed the need for defining a difference between the concepts of trust and credibility; quite often they are used interchangeably or combined as one concept. Further, they have detailed the “laundry lists of factors” that have been used at various times to determine what assists or detracts from source credibility, with little effort at standardization [71–73]. As Tretin and Musham [74] have noted, trust is a response that is to some extent tied to the perception of credibility, but not necessarily the only or sometimes the most appropriate response. Research has shown the trustworthiness of people’s personal doctor to be generally high, but their credibility when it came to such issues such as environmental health risks (in terms of how well-informed they were) was generally lower [50]. Metlay [75] also suggested that, depending on situational concerns, two more or less unrelated factors, which he labeled as either affective or competence components, can influence the level of public trust. Indeed, in public health and risk communication research, knowledge is

not always a preeminent factor in trustworthiness; sources knowledgeable about technological risks may sometimes be considered to be the least trustworthy (e.g., industry spokespeople), while unofficial opinion leaders could be accorded greater credibility [46]. Indeed, the findings of Jungermann *et al.* [76] suggested the pitfalls of simply looking at different sources without providing their context and individual comparisons. Some interesting research by Steel *et al.* [77] concluded that values influenced the amount of trust placed in a source of information. Gunther [78] found that opposing social groups (e.g., different political parties) could both find a given message biased, but in opposite directions, supporting “the view that a significant portion of perceived bias stems from causes other than special knowledge” (p. 161).

INVOLVEMENT WITH AN ISSUE AND SOURCE CREDIBILITY

Gunther [78] concluded that credibility is more a function of involvement than of other variables examined in the past. Instead of credibility being the property of the source, it may be more importantly related to the individual and the situation.

Additionally, Sternthal *et al.* [79] found that involvement in an issue mediates the effects of source credibility. Slater [80] noted that the degree of involvement has “emerged as the crucial contingency variable” in much of the persuasion effects research because of its predictive variation in message processing (p. 125). It has been suggested that involvement’s effects have been variable, sometimes even conflicting, due to varied ways of explication and measurement methods [81,82]. Both Johnson and Scileppi [83] and Rhine and Severance [84] noted that, when involvement with an issue was low, a highly credible source was more persuasive than a low-credibility source. Concurrently, when involvement in the issue was high, credibility did not significantly affect persuasiveness. Consequently, those who are most highly involved with a message are more likely to evaluate the quality of

the arguments contained in the message itself [85]. The less involved will, in turn, form opinions about the message based on surrounding cues of the message, such as the credibility of the source; see also Gunther [62] and Walsh-Childers *et al.* [86]. However, Sprecker [87] found that the more highly involved one is with a subject, the more credible the perception of the source (in this context, a scientist).

McComas and Trumbo [70] have observed that, when it comes to the study of trust and credibility, “depending on the tools of measurement as well as the context of the study, researchers may find very different results” (p. 471).

COGNITIVE SIMPLICITY SEEKING AND ASSESSMENT OF TRUST

Kasperson *et al.* [10] have observed that “many psychological, political, and economic perspectives conceptualize trust very narrowly in terms of individual cognition and rational, calculative behavior” (p. 167). An alternate approach of Barber [31] viewed trust as part of the need we all have to “reduce complexity” in social life. Fukuyama [25] notes that most people are simply habituated to a certain minimal degree of honesty; “gathering the necessary information and considering possible alternatives is itself a costly and time-consuming process, one that can be short-circuited by custom and habit” (p. 36). Whether to sneak out of a restaurant without paying the bill is one example; whether to be polite to a stranger is another.

The search for cognitive simplicity as an explanation for the process of acquiring and maintaining trust, led Nisbett and Ross [88] to maintain that when people have to contend with a multitude of facts and values when making a decision about risk, they simplify. Rather than attempt to think their way through to comprehensive, analytic solutions to decision-making problems, they instead rely on strategies such as habit, tradition, neighbors, media, or general rules of thumb. Several studies have also suggested that, if subjects believe that the source’s position on a topic (e.g., risks and benefits from a new technology) was influenced by their background

(i.e., personal history/affiliation and/or attitude toward the topic), then this could lead to a perception of the source as both biased and lacking in credibility and, therefore, untrustworthy [89]. If, however, they believe that the source was influenced by factual evidence alone, they would view him/her as unbiased, credible, and trustworthy [60,90].

Earle and Cvetkovich [45] have further extended the conceptualization of the search for cognitive simplicity as part of a process of acquiring and maintaining trust. They viewed much of the research outlined earlier as a somewhat simplistic rendering of how the process of trust is formulated and operates within society. Earle and Cvetkovich [45] concluded that much research on trust has employed static and unidimensional analyses, with the dualism between competence (expertise) and (fiduciary) responsibility at its core. Under such a traditional interpretation, as was explored, for example, by Ruscio [91], trust forms part of a bridge to representative democracy. If the citizens' elected representative is proven to be incompetent or irresponsible, then the citizens' trust could be "lost."

Like Barber [31] and Earle and Cvetkovich [45] believed that trust serves as a tool to satisfy an integral need we have to reduce complexity in our environment. They reasoned that when making a social judgment, "an individual in effect moves from State A (in which a person is faced with an environment that threatens to overwhelm him with complexity) to State B (in which the cognitive demands of the individual's environment are reduced to a manageable size). For the individual who makes the social trust judgment, trust acts as a bridge from State A to State B, from disequilibrium (an unbalanced, "nonnormal" state) to equilibrium (a balanced, "normal" state)" (p. 106). They maintained that the conventional monitoring process model for competence and responsibility would necessitate the individual remaining at least minimally engaged in some form of continuous supervision of information, and then be able to mindfully integrate it. At the same time, the cognitive, emotional, and behavioral demands this would place on the individual could be viewed

as substantial. Therefore, the function of trust is to reduce complexity through the acceptance of risk in exchange for "forms of cooperation which do not pay off immediately and which are not directly visible as beneficial" [92, p. 24]. Some corollary evidence supports this; individuals are often seekers of cognitive simplicity, only accepting complexity when highly motivated under certain circumstances [93,94].

In moving away from a concept of a rational decision-making process for trusting to one that reflects the need for reducing cognitive complexity, several strategies can be considered. One stratagem involves possible heuristic mental models. Herbert Simon's [95] notion of "satisficing" is but one example. The decision process for determining who or whether to trust, while concurrently deciding upon the veracity of a risk to oneself or others, may be explained by these "cognitive shortcuts." More recent work of Shah and Oppenheimer [96] on choice heuristics used in trust (since trust essentially involves a preference among options that lack a correct answer) has focused on the difficulty of retrieving cues and integrating the information associated with those cues, while concurrently examining all other alternatives. The various ways in which heuristics reduce the effort involved in judgments of trust and levels of trustworthiness is especially realized in the similarity heuristic, the notion that a perceived similarity between oneself and others leads to more positive judgements, including affinities to groups with identities similar to one's own [97], and homogeneous goals and objectives tied to value similarity (to be explored next).

THE LESSENING OF COMPLEXITY THROUGH VALUES

Aaron Wildavsky [98] has suggested that "individuals use a cognitive screen in which the individual making the risk assessment is first deemed trustworthy or not whereupon the finding of riskiness or safeness follows. But how do individuals determine who to trust?" (p. 182). Wildavsky [99] characterized social trust as a resilient strategy

that seeks to reduce cognitive complexity (while at the same time increasing social benefits) by taking risks. To trust, according to Wildavsky, is to risk. Wynne [100] has argued that an accounting of an individual's personal constructs tied to how socially dependent they perceive themselves to be upon other individuals, institutions, or organizations within a given situation, especially under circumstances tied to mediated information, is an important place to start and must be given priority in any research examining trust. Wildavsky [98,99,101] and Earle and Cvetkovich [45,102,103] have extended this reasoning further and have concluded that a better and more cogent theoretical explanation for how we develop trust in our sources of information, including the institution(s) that the sources may represent, must include values as the essential intervening variable. For, when a close symmetry of values exists between the source of information about a risk and the message receiver, much less thought is required in order to place one's trust in the source itself. In other words, we trust people we take to be similar to ourselves. This, according to Wildavsky [101] explains how "the social filter enable[s] people who possess only inches of facts to generate miles of preferences?" (p. 8). According to Wildavsky, it is not a conscious, rational thought process. Value similarity can also directly affect cooperation [104]. Jenkins-Smith [105] has even suggested that an individual's values can act as a kind of cognitive filter to screen information from which verbal images are constructed. Wildavsky [101] maintained that people can know what they believe or whom they trust without knowing how the belief is derived. By mediating their perceptions through their values, "people can grab on to any social handle to choose their preferences. All they need are aids to calculation" (p. 9). Consequently, who (or whether) people trust could be based largely on the shared values of the person, community, or institution that will potentially be the beneficiary of that trust. This is especially urgent when sizing up a risk about which we possess little knowledge or with which we have minimal personal involvement (which is true of many risks),

and could be both a predictor of what news stories we pay attention to at the outset and whether we then choose to apply further cognitive processes to an analysis of the stories themselves. McLeod *et al.* [106] suggested some conceptual justification for this avenue of research when they reported that values influenced media usage and interpersonal communication patterns.

Another approach employing values as a mediating variable, the Salient Value Similarity model [107–109] hopes to predict trust if salient values are similar and distrust if salient values are dissimilar by construing trust as a social emotion elicited by a situation that implies the question, "Should I rely on this person?"

RISK AND THE IMPORTANCE OF ASSESSING BENEFITS

Lastly, while the modern term for risk has evolved to refer to negative outcomes, perceived *benefits* still matter. Negative outcomes are, after all, usually only half of the equation. Benefits need not be material goods; convenience would be a typical example of an "intangible" benefit. The importance of benefits for our understanding of how the multifaceted processes of social interaction take place within trust-building and trust-destroying contexts would seem apparent. Research by Siegrist [69] and Siegrist *et al.* [109], for example, has shown that trust has an impact on both perceived risk and perceived benefit. Social trust was positively related to perceived benefit but negatively related to perceived risk. Despite the often-noted reduced tolerance for risk by women, in general, when trust and benefits were controlled, no difference between genders was found. However, when the level of trust was controlled for, women were more likely than men to question the perceived utility of science. As in Siegrist [69,110] also demonstrated that trust in companies and scientists conducting research in gene technologies had a strong effect on the overall levels of risk and benefit perceived to be associated with those technologies.

SUMMARY

We have explored the many varied approaches to studying trust. As with any review, the scope of this review is necessarily limited. It attempted to present some of the most influential research conducted within a number of varied fields of study and applied to it risk analysis, risk management, risk perception, and risk communication.

TWO-STAGE STOCHASTIC INTEGER PROGRAMMING: A BRIEF INTRODUCTION

SHABBIR AHMED

H. Milton School of Industrial and Systems Engineering, Georgia Institute of Technology, Atlanta, Georgia

INTRODUCTION

A standard form for a two-stage stochastic integer program (SIP) is as follows:

$$\begin{aligned} \min_x \quad & c^\top x + \mathbb{E}_P[Q(x, \omega)], \\ \text{s.t.} \quad & Ax = b, \\ & x \in \mathbb{R}_+^{n_1-p_1} \times \mathbb{Z}_+^{p_1}, \end{aligned} \quad (1)$$

where

$$\begin{aligned} Q(x, \omega) := \min_y \quad & q^\top y, \\ \text{s.t.} \quad & Wy = h - Tx, \\ & y \in \mathbb{R}_+^{n_2-p_2} \times \mathbb{Z}_+^{p_2}. \end{aligned} \quad (2)$$

Above, n_1, n_2, p_1, p_2 are nonnegative integers with $p_1 \leq n_1$ and $p_2 \leq n_2$, x represents the first-stage decisions and y represents the second-stage decisions, and ω represents the uncertain data for the second stage (the parameters (q, h, T) are actual realization of the random data) with known distribution P . Throughout, we assume that the matrix W is deterministic. Much of the structural results in SIP are for this case. Problem (1) seeks a first-stage decision that minimizes first-stage cost and the *expected* cost of second-stage (recourse) decisions. Note that both first- and second-stage variables are restricted to be mixed integers ($\mathbb{R}$ and $\mathbb{Z}$ denote reals and integers, respectively). If the second-stage variables are continuous (i.e., $p_2 = 0$) then problem (1) involves minimizing a convex objective subjected to mixed-integer constraints. Much of the theory and algorithms for two-stage stochastic

linear programs (LP) (that do not rely on convexity of the first-stage constraints) are then applicable. By two-stage SIPs, we refer to problems where $p_2 > 0$.

A variety of applications in energy planning [1], manufacturing [2], logistics [3], and so on, can be formulated as two-stage SIPs of the form given in Equation (1). In this article, we briefly review some important progress in theory and algorithms for solving Equation (1). There has been significant development in extensions of the two-stage SIP framework; for example, to multistage setting [4] and involving risk averse objectives [5]. However, this article is limited to models of the form (Eq. 1).

STRUCTURE

In this section, we discuss the structure of the expected value function

$$\mathbb{E}_P[Q(x, \omega)],$$

where Q is given by Equation (2). Consider first the value function of a deterministic mixed-integer program (MIP) as a function of the objective and right-hand side vectors

$$\begin{aligned} \Phi(q, t) := \min_y \quad & q^\top y, \\ \text{s.t.} \quad & Wy = t, \\ & y \in \mathbb{R}_+^{n-p} \times \mathbb{Z}_+^p, \end{aligned} \quad (3)$$

where W is a $m \times n$ matrix, and t is an m -vector. We make the following assumptions:

1. For every $t \in \mathbb{R}^m$, there exists $y \in \mathbb{R}_+^{n-p} \times \mathbb{Z}_+^p$ such that $Wy = t$;
2. The entries of W are integers.

Assumption 1 guarantees that MIP Equation (3) is feasible for all $t \in \mathbb{R}^m$, and assumption 2 guarantees that Equation (3) has an optimal solution, if it is feasible and bounded. It is sufficient to assume that W is rational; however, we assume integrality for the ease of exposition. Let us

Figure 1. Objective function of a small SIP.

denote $\mathcal{Q} := \{q : \Pi(q) \neq \emptyset\}$, where $\Pi(q) := \{\pi \in \mathbb{R}^m : W^\top \pi \leq q\}$. Note that $\mathcal{Q}$ is a closed convex set in $\mathbb{R}^n$.

Theorem 1.

- (a) The value function $\Phi(\cdot, \cdot)$ is lower semi-continuous over $\mathcal{Q} \times \mathbb{R}^m$.
- (b) Given $t \in \mathbb{R}^m$, the function $\Phi(\cdot, t)$ is continuous over $\mathcal{Q}$; and given $q \in \mathcal{Q}$ the function $\Phi(q, \cdot)$ is lower semicontinuous over $\mathbb{R}^m$,
- (c) Given $q \in \mathcal{Q}$ the function $\Phi(q, \cdot)$ is continuous over $\mathbb{R}^m$ except over (at most) a countable union of hyper-planes.
- (d) Given $q \in \mathcal{Q}$ the function $\Phi(q, \cdot)$ is sub-additive over $\mathbb{R}^m$, that is, $\Phi(q, t^1 + t^2) \leq \Phi(q, t^1) + \Phi(q, t^2)$.
- (e) Given $t \in \mathbb{R}^m$, the function $\Phi(\cdot, t)$ is concave over $\mathcal{Q}$.

Next, we consider the structure of $\mathbb{E}_P[Q(x, \omega)]$. This function is given by the expectation of the MIP value function $Q(x, \omega) = \Phi(q, h - Tx)$ with respect to the distribution P of the data $\omega = (q, h, T)$.

Theorem 2. In addition to assumptions 1 and 2, assume that the random set $\Pi(q)$

is nonempty with probability one, $\mathbb{E}[||q|| ||h||] < +\infty$ and $\mathbb{E}[||q|| ||T||] < +\infty$. Then, the expected value function $\mathbb{E}_P[Q(x, \omega)]$ is well defined, real-valued, and lower semi-continuous on $\mathbb{R}^{n1}$.

The above result establishes sufficient conditions for the expected value function to be well defined and lower semicontinuous. Apart from this continuity property, very little can be said of the structure of expected value functions of MIPs, in general. Figure 1 illustrates the objective function $c^\top x + \mathbb{E}_P[Q(x, \omega)]$ of a small instance of Equation (1) with $n_1 = 2$. We see that the objective function has none of the desirable properties for optimization. It is nonconvex and even discontinuous.

When the distribution of the ω is absolutely continuous, that is, it has a density function, then it can be further shown that $\mathbb{E}_P[Q(x, \omega)]$ is continuous on $\mathbb{R}^{n1}$, however, it is in general nonconvex.

CHALLENGES AND PROGRESS

There are three levels of difficulty in solving SIPs of the form (1).

1. Evaluating the second-stage cost for a fixed first-stage decision and a

particular realization of the uncertain parameters. Note that this involves solving an instance of the second-stage problem (Eq. 2), which may be an NP-hard integer program (IP) and involve significant computational difficulties.

2. *Evaluating the expected second-stage cost for a fixed first-stage decision.* If the uncertain parameters have continuous distribution, this involves integrating the value function $Q(x, \cdot)$ of an IP, and is, in general, impossible. If the uncertain parameters have a discrete distribution, this involves solving a (typically huge) number of similar IPs.
3. *Optimizing the expected second-stage cost.* As seen in the section titled “Structure,” the value function of an IP is nonconvex and often discontinuous. Consequently, the expected second-stage cost function $\mathbb{E}[Q(\cdot, \omega)]$ is nonconvex in x . The optimization of such a complex objective function poses severe difficulties.

In the following sections, we briefly mention some of the theoretical and algorithmic progress toward addressing the aforementioned difficulties in two-stage stochastic IP.

Difficulty 1

It is typically assumed that a *single* evaluation of the second-stage problem is somehow tractable. Without this assumption, very little progress in optimizing the expected value of this IP is possible. There has been some work in obtaining approximate solutions to SIPs through approximate solutions to the integer second-stage problem [2].

Difficulty 2

Let us now consider the difficulty of evaluating the expected value of the second-stage IP $\mathbb{E}[Q(x, \omega)]$ for a given first-stage decision x . As mentioned earlier, if the distribution of the uncertain parameters is continuous or if, in case of discrete distributions, the number of possible realizations is extremely large, then it is practically impossible to evaluate $\mathbb{E}[Q(x, \omega)]$ exactly. In this case, one has to resort to approximating the underlying

probability distribution by a manageable distribution.

For example, if the underlying distribution is continuous, one may approximate it via discretization. Theoretical stability results for SIPs [6,7] suggest that if the approximate distribution is not too “far” from the true distribution, then the optimal solution to the SIP involving the approximate distribution is close to the true optimal solution.

Alternatively, one may use statistical estimates of the expected value function via Monte Carlo sampling. This can be done in one of two ways. In *interior sampling* approaches, the estimation of $\mathbb{E}[Q(x, \omega)]$ is carried out *within* the algorithm used to optimize this function. For example, in the *stochastic branch and bound algorithm* [8], the feasible domain of the first-stage variables x is recursively partitioned into subsets, and statistical upper and lower bounds on the objective function $c^\top x + \mathbb{E}[Q(x, \omega)]$ over these subsets are obtained via sampling. These bounds are used to discard inferior subsets of the feasible domain, and to further partition the promising subsets to eventually isolate a subset containing an approximate optimal solution. In *exterior sampling* approaches, the sampling and optimization are decoupled. A Monte Carlo sample of the uncertain parameters is generated, and the expectation objective in the problem is replaced by a sample average. The resulting approximation of the problem is then solved, and its solution serves as a candidate solution to the true problem. By repeating the sampling-optimization procedure several times, it is possible to obtain statistical confidence intervals on the obtained candidate solutions. It can be shown that the number of samples needed to get a fairly accurate solution with high probability is not too large. Discussion of theoretical and algorithmic issues pertaining to the above approach in the context of SIP can be found in Refs 9 and 10.

Regardless of how the underlying distribution is approximated, an evaluation of the expected second-stage objective value (under the approximate distribution) requires solving many similar IPs. Owing to the absence

of a computationally useful duality theory for IP, it is very difficult to take advantage of the similarities in the different second-stage IPs. When the second-stage variables are pure integers, several proposals for using Gröbner basis and other test set-based methods from computational algebra for exploiting IP problem similarity have been put forth in Refs 11–13. For the case of mixed-integer subproblems, if a cutting plane method is used, then under some conditions, it is possible to transform a cut (or a valid inequality) derived for one of the second-stage subproblems into a cut for another subproblem by exploiting similarity [14,15].

Difficulty 3

Much of the development in SIP has been toward the difficulty of optimizing $f(x) := c^\top x + \mathbb{E}[Q(x, \omega)]$, that is, the sum of the first-stage and the expected second-stage costs. We classify these developments as follows:

Convex Approximations of the Value Function. Consider an SIP with *simple integer recourse* with only right-hand side uncertainty, that is, q , T are deterministic; the second-stage problem has a special structure such that the value function Q is separable and is given by

$$Q(x, \omega) = \sum_{i=1}^m \phi_i(h_i - T_i x),$$

and each separable piece ϕ_i is of the form

$$\phi(t) = q^+ [t]_+ + q^- [t]_-, \quad t \in \mathbb{R},$$

where $[t]_+ = \max\{0, [t]\}$ and $[t]_- = \max\{0, -[t]\}$. In this case, a single evaluation of $f(x)$ is easy, however, owing to the nonconvex nature of ϕ , the function $f(x)$ is difficult to optimize. Fortunately, it has been shown [16] that an expectation of the continuous counterpart of the simple integer recourse function $Q(x, \omega)$ (i.e., where the recourse variables are continuous instead of being discrete valued) under a particular class of distributions of ω provides the tightest convex underestimator for $\mathbb{E}[Q(x, \omega)]$ over its entire domain. Recently, similar

results for constructing convex approximations of general integer recourse functions (SIPs involving pure integer second-stage variables) by perturbing the underlying distribution have been obtained [17]. These convex approximating functions are amenable to optimization and can be used to provide strong lower bounds within some of the algorithms for optimizing $f(x)$, discussed next. An open problem is the refinement of these approximations using additional constraints on the first-stage variables, for example, bounds on x .

Stagewise Decomposition Algorithms. This class of algorithms adopt the natural viewpoint of optimizing the objective function $f(x) := c^\top x + \mathbb{E}[Q(x, \omega)]$ over the set of feasible first-stage decisions (say denoted by X). Note that $\mathbb{E}[Q(x, \omega)]$ is not available in closed-form, nor is it suited for direct optimization. Typical algorithms in this class progress in the following manner. In an iteration i , the algorithm builds and/or refines a computationally tractable approximation (typically an underestimator) $\hat{Q}_i(x)$ of $\mathbb{E}[Q(x, \omega)]$. The underestimating function $c^\top x + \hat{Q}_i(x)$ is optimized with respect to the first-stage variables (this optimization problem is often referred to as the *master problem*) to obtain a lower bound on the true optimal objective value as well as to provide a candidate first-stage solution x^i . Corresponding to the candidate solution, the second-stage expected value function $\mathbb{E}[Q(x^i, \omega)]$ is evaluated. Assuming that the distribution of ω is discrete, this step involves independent solution of the second-stage problems for each realization of ω , allowing for a computationally convenient decomposition. The value $c^\top x^i + \mathbb{E}[Q(x^i, \omega)]$ provides an upper bound on the optimal objective value. The evaluation of $\mathbb{E}[Q(x^i, \omega)]$ also provides information on how the approximation $\hat{Q}_i$ is to be updated/refined to $\hat{Q}_{i+1}$ for the master problem of iteration $i+1$. The process continues until the bounds have converged. The details of the various stagewise decomposition algorithms differ mainly in how the approximation $\hat{Q}_i$ is constructed and updated.

For SIPs with binary first-stage variables and mixed-integer second-stage variables,

the *integer L-shaped method* [18] approximates the second-stage value function by linear “cuts” that are exact at the binary solution where the cut is generated and are underestimates at other binary solutions. The optimization of the master problem, that is, optimizing $c^\top x + \hat{Q}_i(x)$ with respect to the first-stage binary variables, is carried out via a branch-and-bound strategy. As soon as a new first-stage binary solution is encountered in the branch-and-bound search, the second-stage subproblems are solved to generate a new cut and to refine the approximation $\hat{Q}_i$. The integer L-shaped method requires that the second-stage integer problems (corresponding to the current candidate first-stage solution x^i) are all solved to optimality before a valid cut can be generated. Recall that typical IP algorithms progress by solving a sequence of intermediate LP problems. Using disjunctive programming techniques, it is possible to derive cuts from the solutions to these intermediate LPs that are valid underestimators of $\mathbb{E}[Q(x, \omega)]$ at all binary first-stage solutions [15, 19]. This avoids solving difficult integer second-stage problems to optimality in all iterations of the algorithm, providing significant computational advantage.

For SIPs where the first-stage variables are not necessarily all binary, dual functions from the second-stage IP can, in principle, be used to construct cuts to build the approximation $\hat{Q}_i$ [20]. Owing to the nonconvex nature of IP dual functions, the cuts are no longer linear, resulting in a nonconvex master problem. If the second-stage variables are pure integers (and the first-stage variables are mixed-integers), then it can be shown that $\mathbb{E}[Q(x, \omega)]$ is a piecewise constant over subsets that form a partitioning of the feasible region of x [12]. Optimization of $c^\top x + \mathbb{E}[Q(x, \omega)]$ over such a subset is easy. This leads immediately to a scheme where the subsets are enumerated, and the one over which the objective function value is least is chosen. By exploiting certain monotonicity properties, the subsets can be enumerated efficiently within a branch-and-bound strategy [21]. Additional properties of the MIP value function $Q(x, \omega)$, such as subadditivity, can be used to improve the method [22].

Scenariowise Decomposition. Assuming the distribution of ω is discrete, that is the random parameter takes one of a finite set of values (scenarios) $\{\omega_1, \dots, \omega_S\}$ having probabilities $\{p_1, \dots, p_S\}$, the two-stage SIP can be reformulated as follows:

$$\begin{aligned} \min \quad & \sum_{s=1}^S p_s (c^\top x_s + q_s^\top y_s) \\ \text{s.t.} \quad & Ax_s = b \quad s = 1, \dots, S \\ & T_s x_s + W_s y_s = h_s \quad s = 1, \dots, S \\ & x_s \in \mathbb{R}_+^{n_1-p_1} \times \mathbb{Z}_+^{p_1} \quad s = 1, \dots, S \\ & y_s \in \mathbb{R}_+^{n_2-p_2} \times \mathbb{Z}_+^{p_2} \quad s = 1, \dots, S \\ & x_1 = x_2 = \dots = x_S. \end{aligned}$$

Note that copies of the first-stage variable have been introduced for each scenario. The last constraint, known as the *nonanticipativity* constraint, guarantees that the first-stage variables are identical across the different scenarios. Consider the Lagrangian dual problem obtained by relaxing the nonanticipativity constraints through the introduction of Lagrange multipliers. Note that for a given set of multipliers, the problem is separable by scenarios. Thus, the dual function can be evaluated in a decomposed manner. Optimization of the dual function can be performed using standard nonsmooth optimization techniques. However, owing to the nonconvexities, there exists a duality gap, and one needs to resort to a branch-and-bound strategy to prove optimality [23].

Cuts for Deterministic Equivalent MIP. If the number of scenarios (assuming a finite distribution setting) is not astronomical then, a possible approach is to directly solve the deterministic equivalent MIP,

$$\begin{aligned} \min \quad & c^\top x + \sum_{s=1}^S p_s q_s^\top y_s \\ \text{s.t.} \quad & Ax = b \\ & T_s x + W_s y_s = h_s \quad s = 1, \dots, S \\ & x \in \mathbb{R}_+^{n_1-p_1} \times \mathbb{Z}_+^{p_1} \quad s = 1, \dots, S \\ & y_s \in \mathbb{R}_+^{n_2-p_2} \times \mathbb{Z}_+^{p_2} \quad s = 1, \dots, S \end{aligned}$$

using an off-the-shelf solver such as CPLEX or EXPRESS.

One of the most important features of these solvers is the generation of cutting

planes by analyzing the polyhedral structure of the problem. Such cuts significantly improve the LP relaxation of the problem, and expedite LP-based branch-and-bound search. Typically, such cuts are generated by analyzing a single row of the constraint system and do not combine information from multiple rows. In an SIP, the constraint system is repeated with small changes for each scenario. Thus, it is possible to effectively combine cuts from multiple rows corresponding to different scenarios [24]. Such cuts have been shown to significantly improve performance over single row cuts. An open issue is that such multirow cuts link second-stage variables across multiple scenarios, and hence destroy decomposability. Algorithmic techniques that can bypass this issue pose an important challenge.

CONCLUDING REMARKS

This article offers a very limited view of some of the theoretical and algorithmic concepts in SIP. The concepts alluded to here have been significantly enriched and extended in recent years. We have not discussed the large number of important developments in application-specific areas of SIP (see Ref. 25 for a bibliography of applications of SIP), and have also omitted the important progress-made in approximation algorithms for SIP. We hope that this simple introduction will pique the readers' interest toward further exploration of SIP. More detailed surveys on stochastic integer programming can be found in [26,27,28].

TWO-STAGE STOCHASTIC PROGRAMS: INTRODUCTION AND BASIC PROPERTIES

JOHN R. BIRGE

University of Chicago Booth School of
Business, Chicago, Illinois

Practical decision making often requires a current action before the resolution of some uncertainty and possibly some future action. The mathematical formulation of this basic decision sequence is known as a *two-stage stochastic program*. Examples range across all applications of operations research methodology, including production, prices, and inventory control required before demand can be observed, investment and borrowing that must be made before returns can be observed, and products and services that are designed and sold before their performance is known. A prototypical example is the *news vendor* problem in which a news vendor must purchase a quantity of papers before knowing the demand for those papers. The vendor's future action after observing the demand is then to sell or salvage the papers that were bought earlier.

To describe this model, let x represent the number of papers initially purchased at a unit price c . Let the selling price of the papers be q , the salvage value of any left-over papers be r , the demand with realization $\xi \in \Xi$ have a distribution function F , and that the news vendor is risk-neutral and indifferent between payoffs before and after the resolution of the demand uncertainty (i.e., so that future cash flows are not discounted relative to current cash flows). A two-stage formulation of this model is

$$\min_{x \geq 0} (c - q)x + \mathbb{E}[(q - r)y(\xi)] \quad (1)$$

$$\text{subject to } x - y(\xi) \leq \xi,$$

$$y(\xi) \geq 0, \text{ a.s.}, \quad (2)$$

where $\mathbb{E}$ denotes the mathematical expectation with respect to the random demand variable ξ , a.s. indicates that the constraints hold almost surely, and $y(\xi)$, the number of unsold units, is known as the *recourse* action. In this formulation, the profits on x are counted in the first period (or stage) before the realization of demand, then removed in the second period, and replaced with the salvage value in the event of insufficient demand.

The general two-stage stochastic program maintains the form of Equation (1) with a first-stage decision $x \in \mathcal{N}^1$, followed by the realization of a random vector $\xi \in \mathcal{N}^k$ and a recourse action $y(\xi) \in \mathcal{N}^2$. The formulation also includes an explicit set of first-stage constraints given by X such that $x \in X$ and second-stage constraints given by $Y(x, \xi)$ such that $y(\xi) \in Y(x, \xi)$. The general formulation then appears as

$$\begin{aligned} \min_{x \in X} \quad & c(x) + \mathbb{E}[q(y(\xi), \xi)] \\ \text{subject to} \quad & y(\xi) \in Y(x, \xi) \text{ a.s.}, \end{aligned} \quad (3)$$

where c and q now represent general functions of the decisions. The constraints in this case are often given by an explicit system of linear and nonlinear equations and inequalities but may also include integrality restrictions and conditions that may hold with a certain probability as *probabilistic* or *chance constraints* (see **Models and Basic Properties**).

The formulation in Equation (3) is often further simplified by defining a *conditional recourse* or *second-stage value function* as

$$Q(x, \xi) = \min_{y \in Y(x, \xi)} q(y(\xi), \xi), \quad (4)$$

and an *unconditional recourse* or *expected second-stage value function* as

$$Q(x) = \mathbb{E}_\xi [Q(x, \xi)] = \int Q(x, \xi) F(d\xi). \quad (5)$$

With this definition, Equation (3) becomes

the *deterministic equivalent program*:

$$\min_{x \in X} c(x) + Q(x), \quad (6)$$

which now has the form of a deterministic optimization problem.

In some cases, such as the news vendor example, Equation (6) can be solved directly (even analytically) without using the structure inherent in Equation (3), but exploiting the structure of Equation (3) is often necessary to obtain an efficient computational procedure. The properties of solution existence, optimality conditions, and alternative equivalent formulations (such as dual programs) give these fundamental structural results that then enable various computational schemes. The most basic of these properties appear below. (See Bazaraa and Shetty [1] for more details.)

SOLUTION EXISTENCE

The main question in this case is whether there exists some $x^* \in X$ such that $c(x^*) + Q(x^*) = \min_{x \in X} c(x) + Q(x)$. This may not be the case in the familiar situation that the value in Equation (6) is unbounded below over $x \in X$ as, for example, in the news vendor when the possible demand realizations, Ξ , are unbounded and the salvage value $r = q$. In other cases, $c(x) + Q(x)$ may also only approach an infimal value asymptotically as in the case where the news vendor also earns no profit on sales ($c = q$) but pays a penalty $p > 0$ for each unit of demand that is not satisfied, that is Equation (3) is

$$\min_{x \geq 0} \mathbb{E}[py_2(\xi)] \quad (7)$$

$$\text{subject to } x - y_1(\xi) + y_2(\xi) = \xi,$$

$$y_1(\xi), y_2(\xi) \geq 0, \text{ a.s.}, \quad (8)$$

where $1 - F(\xi) > 0$ for any $\xi < \infty$. In this case, the infimal value of (7) is zero, but this is only achieved as $x \rightarrow \infty$. In this case, the infimum of $f(x) = c(x) + Q(x)$ is not obtained over X because the direction $z = +1$ is such that $x + z \in X$ for any $x \in X$ and $f(x + z) - f(x) < 0$ for any $x \in X$. In terms of convex analysis (see Rockafellar [2] and *Nonlinear Conjugate*

Gradient Methods), z is a *recession direction* of both X and f . If f is closed and proper (i.e., nowhere $-\infty$ and not identically $+\infty$ convex function), X is a nonempty, closed, convex set, and f and X do not share any common recession directions, convex analysis [[2], Theorem 27.3] gives that the minimum in Equation (3) is attained. We can state these conditions for Equation (3) as follows.

Theorem 1. *If X is a nonempty, closed convex set, c and Q are both closed proper convex functions, and (i) if X is bounded or, (ii) for every z such that $x + z \in X$ for every $x \in X$, $\exists \epsilon > 0$ and $x \in X$ such $Q(x + z) - Q(x) > \epsilon$, then the minimum in Equation (3) is attained at some $x^* \in X$.*

Since Q may be hard to find explicitly, it is often useful to be able to verify that a minimum can be attained using only the properties of c and q . In this case, it is most convenient that $Q(x) = +\infty$ only when $\text{prob}\{\xi | Q(x, \xi) < +\infty\} < 1$, since then, if $Q(\cdot, \xi)$ satisfies the condition in place of Q in Theorem 1 for each ξ , attaining a minimum can be assured. This equivalence of the feasibility (finite values) in the conditional and unconditional recourse functions is the case whenever the second moments of all the random parameters exist if q is linear ($q(y(\xi), \xi) = q(\xi)^T y(\xi)$) and Y can be written as $Y(x, \xi) = \{y \geq 0 | Wy + T(\xi)x = h(\xi)\}$ (which is known as *linear, fixed recourse* when W does not depend on ξ) [1, Proposition 3.1.2].

OPTIMALITY CONDITIONS

When an optimal solution to Equation (3) exists and is attained, it is useful to have conditions that are necessary and sufficient for optimality. For these properties, assume X , c , and Q are all convex and a regularity condition is satisfied (such as a common point in the relative interior of the effective domains of c and Q , where the *effective domain* of a function f is given as $\text{dom } f = \{x | f(x) < \infty\}$), the basic optimality conditions from convex analysis [see Bazaraa and Shetty [3] (Theorem 3.4.3)] can then apply so that $x^* \in X$

is an optimal solution if and only if

$$0 \in \partial c(x^*) + \partial Q(x^*) + N_X(x^*), \quad (9)$$

where $\partial f(x^*) = \{v | f(x) + v^T(z - x) \leq f(z), \forall z\}$, the subdifferential set of all subgradients of f at x , and $N_X(x^*) = \{v | v^T(z - x^*) \leq 0, \forall z \in X\}$, the normal cone to X at x^* . When c and Q are differentiable and $X = \{x | g(x) \leq 0\}$ for some $g : \mathbb{R}^{n_1} \rightarrow \mathbb{R}^{m_1}$, where $g = [g_1, \dots, g_{m_1}]$ such that each $g_i, i = 1, \dots, m_1$ is convex and differentiable (and whose effective domain shares a common relative interior point with all other functions), then Equation (9) reduces to the standard Karush–Kuhn–Tucker conditions and there exists multipliers $0 \leq \lambda^* \in \mathbb{R}^{m_1}$ such that

$$\nabla c(x^*) + \nabla Q(x^*) + \sum_{i=1}^{m_1} \lambda_i^* \nabla g_i(x^*) = 0. \quad (10)$$

Although the recourse function $Q(x)$ is generally differentiable (see the result below) when ξ is continuously distributed, implementation often requires a finite representation of ξ ; so, the general representation in Equation (9) is more relevant to two-stage stochastic programs than the standard result in Equation (10). Most often, $Q(x)$ is not differentiable even when $q(y, \xi)$ is differentiable in y for every ξ . The potential for difficulty is that $Q(x, \xi)$ is usually not differentiable in x , although, in many cases, $Q(x, \xi)$ has useful properties for computation. The following [2, Theorems 3.5, 3.6, and 3.11] summarizes these properties for the unconditional and expected recourse functions, Q and $\bar{Q}$, for the case of linear fixed recourse, where ξ is interpreted as the vector of all random components in q , T , and h .

Theorem 2. *If $q(y(\xi), \xi) = q(\xi)^T y(\xi)$, $Y(x, \xi) = \{y \geq 0 | Wy + T(\xi)x = h(\xi)\}$, $Q(x, \xi) > -\infty$ for any x and ξ , and ξ has finite second moments, then*

1. $Q(x, \cdot)$ is piecewise-linear convex as a function of (h, T) for any $x \in X$;
2. $Q(x, \cdot)$ is piecewise-linear concave as a function of q for any $x \in X$;

3. $Q(x, \xi)$ is piecewise-linear convex as a function of x for any $\xi \in \Xi$;
4. if ξ has a finite representation, $Q(x)$ is piecewise-linear and convex;
5. $Q(x) < \infty$ whenever $Q(x, \xi) < \infty$ almost surely;
6. $Q(x)$ is convex in x and Lipschitzian; that is, there exists $K < \infty$ such that $|Q(x) - Q(z)| \leq K\|x - z\|$ for any x and z in $\text{dom } Q$;
7. if $F(\xi)$ is absolutely continuous, $Q(x)$ is differentiable on the interior of $\text{dom } Q$;
8. if $x \in X$, $\partial Q(x) = \mathbb{E}[\partial Q(x, \xi)] + N_{\text{dom } Q}(x)$.

These properties motivate the use of methods based on piecewise-linear convex approximations of Q (see the discussion in Birge and Louveaux [1]) that can also be approximated by sampling ξ [4] (see **Sampling Methods**).

DUAL AND NONANTICIPATIVE FORMULATIONS

These properties also lead to representations of dual programs to Equation (3). For these problems, we can write the Lagrangian dual function (see **Lagrangian Optimization Methods for Nonlinear Programming**) when $X = \{x | g(x) \leq 0\}$ as

$$l(\lambda) = \inf_x c(x) + Q(x) + \lambda^T g(x), \quad (11)$$

to form a dual program:

$$\max_{\lambda \geq 0} l(\lambda). \quad (12)$$

In the fully linear case where $c(x) = c^T x$, $g_i(x) = -a_i^T x + b_i$, where $A = [a_1 \dots a_{m_1}]^T$, $q(y(\xi), \xi) = q(\xi)^T y(\xi)$, and $Y(x, \xi) = \{y \geq 0 | Wy + T(\xi)x = h(\xi)\}$, Result 8 in Theorem 2 can be used by noting that $\partial Q(x, \xi) = \{-\pi(\xi)^T T(\xi)\}$ such that $\pi(\xi)$ maximizes $\pi(\xi)^T (h(\xi) - T(\xi)x)$ over $\pi(\xi)^T W \leq q(\xi)^T$ and by avoiding complications from the normal cone term in the expression for $\partial Q(x)$. This additional term occurs because some elements in $\partial Q(x)$ can be singular multipliers that cannot be expressed as expectations of

multipliers from $\partial Q(x, \xi)$. This potentially unstable situation can be avoided if the problem has a property called *relatively complete recourse* that $Q(x) < \infty$ for all $x \in X$ (or the more restrictive property of *complete recourse* that $Q(x) < \infty$ for any $x \in \mathbb{R}^n$). With the relatively complete recourse property or a finite number of realizations, the Lagrangian dual function in the fixed linear recourse case can be written as

$$l(\lambda) = \begin{cases} E[\pi(\xi)^T h(\xi)] + \lambda^T b & \text{if } c^T - E[\pi(\xi)^T T(\xi)] \\ & -\lambda^T A = 0, \\ & \pi(\xi)^T W \leq q(\xi)^T \text{ a.s.}, \\ -\infty & \text{otherwise,} \end{cases} \quad (13)$$

yielding the dual program:

$$\max b^T \lambda + E[h(\xi)^T \pi(\xi)] \quad (14)$$

$$A^T \lambda + E[T(\xi)^T \pi(\xi)] = c, \quad (15)$$

$$W^T \pi(\xi) \leq q(\xi)^T \text{ a.s.}, \quad (16)$$

$$\lambda \geq 0, \quad (17)$$

which can provide a more efficient structure for computation (particularly for interior point methods (see **Central Path and Barrier Algorithms for Linear Optimization**) as discussed in Birge and Louveaux [[1], Chapter 5]). Nonlinear versions of the dual in Equation (14) can also be useful computationally and constructed using standard convex duality arguments with attention again paid to the possible presence of singular multipliers that can be avoided when relatively complete recourse can be verified.

The major computational difficulty for stochastic programs stems from the evaluation of $Q(x)$ and discovery of potential directions of improvement. Solution methods focus on simplification and approximation of $Q(x)$, using convexity and the subdifferential structure, and on repeated structure and possible similarity among the $Q(x, \xi)$ subproblems. The computational advantages of this aspect

of the two-stage stochastic program are that the Jacobian matrix of the constraints and the Hessian matrix of the objective are sparse (since they do not involve terms directly linking $y(\xi_i)$ and $y(\xi_j)$ when $\xi_i \neq \xi_j$) and often have similar components. For direct optimization, the linear algebra can then be more efficient particularly if solutions of the linear systems recognize and exploit the structure. This observation can also lead to decomposition methods that iterate between solutions with x and $y(\xi)$, with much of the potential effort on $y(\xi)$ solutions performed in parallel. This observation also raises the possibility of decomposing the problem further by allowing x to depend on ξ as $x(\xi)$ but by then adding an explicit constraint, called *nonanticipativity* that can take the form:

$$x(\xi) - E[x(\xi)] = 0, \text{ a.s.} \quad (18)$$

The constraint (18) then becomes the only link between distinct realizations of ξ and can allow for further parallelism by relaxing Equation (18) and placing it into the objective as in Lagrangian relaxation.

The basic properties above also hold for problems with multiple stages where the action–observation–action sequence is repeated many times. These problems present additional computational challenges but the emphasis on identifying convexity, repeated structure, natural sparsity, and finding subgradients can again lead to computational efficiencies.

INTRODUCTION

Using OR models in forest planning has a long tradition. In the 1970s, the US Forest Service started using linear programming extensively for long-range planning of its forests. In that model, Timber RAM [1], decisions were made on when to harvest areas and then to replant them. Also partial harvest and other silvicultural treatments to improve tree growth were considered. Horizons considered were of almost 200 years in duration, so as to include over two tree rotations, using 10-year periods which were aggregated into longer periods as the horizon approached. In these decisions, aggregate characteristics of both, spatial areas and timber species and types were considered. This made sense, given the long range of the plans as well as the general criteria underlying the decisions. Since then, the use of OR tools has been expanded very successfully to different planning and scheduling problems; for instance Epstein *et al.* [2], Martell *et al.* [3], Weintraub *et al.* [4], and in the article titled *Operations Research in Forestry and*

Forest Products Industry. In the 1980s, tactical, medium-range planning started being implemented. Decisions involved defining specific spatial characteristics. In tactical planning, models define specific cutting units to harvest in each period. Decisions are considered only until existing trees are harvested. In this form, for native forests with growth periods of about 80 years, typical horizons are of about 40–50 years. In plantations with growth periods of about 20 years, typical horizons are of about 5 years. At this level, road building, which in native forests leads to about 40% of operating costs, is often included explicitly. Also in the 1980s, concern for the environment grew. Planning models explicitly incorporated these concerns. The most familiar forms expressing habitat protection are the well-known adjacency constraints, which indicate that when one cutting area is harvested (about 40 ha) no neighboring areas can be harvested until the recently harvested area grows for long enough, usually one or two periods. These constraints have been implemented by legislation in North America and Europe, so models to support these decisions incorporate spatial constraints. Since including adjacency or other spatial constraints leads to problems that are combinatorially complex, mostly heuristic algorithms have been implemented (Monte Carlo simulation and, lately, Tabu search or simulated annealing; [5]). In addition, exact algorithms have been developed which have solved moderate size problems [6]. In the late 1980s and 1990s, operational decisions started being implemented in forest firms. These decisions involve short-term practices related to harvesting and transporting logs to destinations such as saw mills, pulp plants or ports for export. One example is the forest firms in Chile, which in the early 1990s successfully implemented several systems for operational purposes [7]. One system supported harvesting decisions on a 45-days horizon, given known demands for logs of different sizes and trees available in different cutting units.

Another model supported decisions on location of harvesting machinery (skidders for flat terrain and cable logging for steep areas) and secondary roads to access the machinery locations. Finally, a transportation model was implemented for daily decisions on scheduling trucks to transport logs from different origins in the forests to the destinations (sawmills, pulp plant, ports, stocking areas). In the last two decades, multiple proposals for operational decisions in other countries such as Sweden, New Zealand, and Canada have appeared in the literature [8,9]. The issue of uncertainty has appeared in the literature mainly since the 1980s. There are varied causes for uncertainty:

- **Market Conditions.** Future prices of different timber products are difficult to predict. Also, the level of demands for a given firm can cause uncertainty. Given the high incidence of transportation costs within the final total cost, the location of a given firm and its main competitors in relation to specific markets is important. So, the behavior of competitors is another source of uncertainty. Note that market uncertainty is important in the long term, in relation to investments; in the medium term, in relation to tactical planning and delivery contracts. In the short term, uncertainty does not play such an important role in market conditions.
- **Growth and Silvicultural Conditions.** There exist sophisticated statistical models to predict future long-term growth of trees under different management conditions. But naturally, there are errors and uncertainties related to this growth. Climate, for example, is one cause of growth uncertainty.
- **Fires and Pests.** In addition to the silvicultural uncertainties for growth, added uncertainties are losses due to fires and pests. In North American native forest for example fires are a significant source of loss of timber, see Martell [10].
- **Short-Term Operational Uncertainties.** These uncertainties are of lesser importance, but need to be analyzed. Simulation models, based on sample lots,

try to predict how much timber will be extracted from a given cutting unit if harvested now. However, there are errors in these estimations. There are also uncertainties for example, in travel times when scheduling truck trips.

The rest of the article is organized as follows: In the next section we discuss three different aspects of uncertainty, and how they have been dealt with. In the section titled "Planning Forest Harvest and Access Road Construction under Uncertainty," we present a specific problem involving tactical planning with market uncertainty. The section titled "Stochastic Programming Approach" discusses these different aspects of uncertainty, and how they have been dealt with. In the section titled "Mixed 0–1 Model" we present one specific case of uncertainty in tactical planning, when the cause of uncertainty is in the market conditions. The next section deals with a case study and we present the conclusions in the final section.

FOREST UNCERTAINTY MODELS

In this section, we discuss the specific aspects of uncertainty and the models and algorithms that have been proposed in the literature. When uncertainty is present, planners and schedulers look for good robust and flexible solutions, which will allow for adequate recourse decisions and lead to good solutions as reality becomes known as time goes by. We will discuss the problems that have been presented in the introductory section, though naturally all aspects of uncertainty are present simultaneously in a given planning time horizon.

Market Uncertainty

Uncertainty related to markets is a major issue in planning. We can view uncertainty as long range, related to major investments, or medium range for tactical planning and operational uncertainty. Long-range uncertainty is vital when considering investments. Long-range market uncertainties reflect demand for saw timber, paper, panels, and other wood products. The investments can be in

large plantations, with horizons of typically 20 years for pine plantations for example, and investment in plants, again with long-range horizons (a pulp plant takes 5 years from planning stage to operation and costs over USD 500 million). OR models have not been really been proposed to handle long-range uncertainty. Typically, scenario analysis has proved to be a tool most used to handle uncertainty, based on long-range harvesting models. Long-range market uncertainty has been approached through real options theory. Insley [11] and Insley and Rollins [12] modeled single and multirotation stochastic optimal harvest problems as call options using a finite difference scheme. Chladna [13] includes carbon emissions permits as revenues in addition to timber. Ibañez and Zapatero [14] solve the stochastic optimal harvest problem via Monte Carlo methodology.

In the case of medium-range investments, explicit uncertainty models have been developed. As was defined, tactical models deal with shorter time periods, where spatial decisions are specified exactly. In the next section we present one case study of a medium-range harvesting and road building problem, where future market conditions present uncertainty. Adaptive optimization of forests is presented [15], see also a description of case studies. In this approach, the decision process can be viewed as a controllable Markov process. Main uncertainties are in market scenarios as well as in silvicultural and managerial issues. Stochastic dynamic programming is the basic tool for this approach.

Short-term uncertainty is present in operational decisions. In relation to markets, there is a need to determine the volumes of different products to be harvested, decisions that will depend on market prices. Uncertainties in relation to markets relate to unexpected demands and sudden variations in prices; in particular, price rises that make it very advantageous to produce additional volumes quickly. The approach in most cases has been to allow for flexibility in the decisions to be made. No specific stochastic approaches have been used in the short-term decisions.

Silvicultural and Growth Uncertainties

Again, we have long-, medium-, and short-term uncertainties since there is natural variability in tree growth. Chance-constrained programs were proposed [16,17], to handle this variability. Typical constraints related to timber production are given as a minimum and maximum production for a given period (usually derived from market demand expectations), or a maximum variation of total volume produced between periods (in general, there are important advantages to having homogeneous production along time). These constraints become probabilistic ones; for example, the probability of satisfying each constraint must be at least 95%. Assuming growth can be represented by a normal probability, these probabilistic constraints yield nonlinear deterministic models. While these models can be solved well for moderate size problems, we are not aware of any actual decision making application. Adaptive management plays an important role in real planning [18]. Forests allow for larger flexibility in adapting to future variability than other fields, such as manufacturing. This is due to the nature of tree growth. Planners may have one plan, but then when real growth becomes known, it is usually not difficult to suitably modify harvest plans. In [19], an example was shown considering two planners: one considers explicitly uncertainty (chance constrained programming) and the other one, a deterministic planner, uses expected values. It was shown in case studies that there was a significant difference in favor of the “stochastic” planner when demand was close to supply possibilities. Short-term main components of uncertainty include data errors in the availability of timber in the areas to be harvested. Simulators based on sample plots have been successful in determining the total production of timber, but not so effective in predicting the amount of timber of different lengths and diameters to be obtained once trees are bucked or cut into pieces. No models are known to explicitly include uncertainty into harvesting models. Errors in predicted amounts are difficult to measure, and actual decision making is basically adaptive and takes advantage of the

flexibility of forests (harvesting a different unit, use different bucking schemes, etc).

Fires and Pests

Martell [10] describes different decision processes related to forest fires. The main problems discussed include the initial attack resource deployment of airtankers and crews of firefighters once a fire has been detected. Proposals have included chance-constrained programming and queueing models to allocate helicopters. Large fire management, which occurs when fires cannot be controlled in the initial attack and escape, are another case of good use of OR tools. In this case, there is important uncertainty in relation to how the fire will spread; this has a stochastic nature. A few models, including stochastic programming-based models, have been developed to support decisions to contain fires but have not been widely used. Long-range decisions involve investments in firefighters and crews and also harvesting patterns to help contain fires. Notice that harvesting areas that are likely to be in the path of large fires converging on valuable land can act as useful firebreaks [20].

Operational Uncertainties

Short-term uncertainty is present in operational decisions. These decisions involve which areas to harvest in the near future (one week, one month, 4 months), how to handle the harvesting machinery, fleet planning, and daily truck scheduling. There are obvious uncertainties here, such as possible machinery or truck failures, travel times for trucks, and so on. In general, these uncertainties have not been incorporated explicitly into models, given the complexities of these models even in the deterministic versions. Robust solutions are usually determined by allowing some expected slack, such as adding a small percentage to expected travel time. Or, in case of daily transportation planning, allowing for a higher number of trucks than the expected need, which are less expensive than the loader machineries (to load logs into trucks), so that the less costly trucks seldom constitute a bottleneck.

PLANNING FOREST HARVEST AND ACCESS ROAD CONSTRUCTION UNDER UNCERTAINTY

The advantages of integrating the processes of planning forest harvest and access road construction in a single mixed 0–1 model were demonstrated [21] by obtaining solutions from 15% to 45% better than with models optimizing the processes separately; see also work by Jones *et al.* [22]. Various studies exist on the different phases of forestry planning [23,24]; for example, the problem of access road construction and timber harvest policies [25]. In essence, the problem can be formulated on the basis of a division of the forest into harvest units that we shall call “cells.” For a chosen time horizon, one must determine for each time period, which cells will be cut, which roads need to be constructed for accessing those cells, and the quantity of wood to be transported from one point to another, to maximize the expected net return under uncertainty in wood selling prices.

Approaches to solving the deterministic (one simple scenario) problem can be found [26], where model strengthening schemes and decomposition techniques such as Lagrangean relaxation are employed to obtain very good solutions in reasonable computation times with low residual gaps. See how deterministic machinery location and road design problems are solved in forestry management [27]. However, the stochastic version of the problem can be formulated as a large-scale structured mixed 0–1 linear program. As such, it is difficult to solve due to its size and the presence of several thousands of 0–1 variables.

In the following, the model for planning forest harvest and access road construction under uncertainty as proposed by Alonso-Ayuso *et al.* [28] is presented. It is a simplified version of the one actually used for planning [26]. The simplification keeps the main elements of the problem and makes it more convenient for highlighting the stochastic nature introduced in the model.

Let us consider a forest divided into a set $\mathcal{H}$ of harvest units or cells. There is a set $\mathcal{O}$ of origins where wood is processed and a set $\mathcal{S}$

of wood exits. Each origin has an associated set of cells $\mathcal{H}_o$. These origins and exits are connected through a set of existing roads, say $\mathcal{R}^E$, and there is the possibility of building several potential roads, say $\mathcal{R}^P$. Other points to be considered are the intersection between roads, $\mathcal{J}$. Note that these elements define a graph where the nodes are $\mathcal{O} \cup \mathcal{S} \cup \mathcal{J}$ and the arcs are $\mathcal{R}^E \cup \mathcal{R}^P$.

For each cell h in $\mathcal{H}$, the following parameters are given:

- a_h^t , productivity of cell h , if it is harvested in period t [m^3/Ha];
- A_h , area of the cell h to be harvested [ha];
- P_h^t , harvesting cost of one hectare of cell h in time period t [dollars/ha].

For each origin o , Q_o^t denotes the unit production cost in time period t [dollars/ m^3]. For each arc (k, l) and time period t , we know the flow capacity, $U_{k,l}^t$ [m^3], and the unit transport cost, $D_{k,l}^t$ [dollars/ m^3]. The construction cost of a potential road in arc (k, l) at time period t [dollars], say $C_{k,l}^t$, is also given.

The uncertainty in the model is due to the wood prices and demand, since these parameters have historically experienced significant fluctuations, as exemplified for pulpwood in Chile between 1994 and 2003, shown here in Fig. 1. This kind of uncertainty can be modeled by a set Ω of scenarios represented in a tree. Figure 2 shows a scenario tree of timber sale price and demand. A *scenario* is a particular realization of uncertainty through the whole time horizon and it is represented by a path from the root to a leaf in the tree. Each scenario has a weight w^ω , that represents the probability that the modeler assigns for this scenario to happen ($\sum_{\omega \in \Omega} w^\omega = 1$).

Each node in the scenario tree defines a group Ω^g of scenarios that are identical up to the stage associated to this node, and, $\mathcal{G}^t$ is the set of scenario groups (nodes) at stage t . (See **Modeling Uncertainty in Optimization Problems** for an introduction to the subject.)

The following parameters for each scenario ω are considered in the model:

- $R_s^{t,\omega}$, sale price at exit s in time period t under scenario ω [dollars/ m^3].
- $\underline{Z}^{t,\omega}, \bar{Z}^{t,\omega}$, lower and upper demand bounds in period t under scenario ω [m^3], respectively.

Stochastic Programming Approach

A key idea in stochastic programming is the nonanticipativity principle [29,30], according to which, if two different scenarios are identical up to a given period in the time horizon, the values of the decision variables must be identical up to that period. That is, the decisions for all scenarios in the same group g are identical up to the stage in which this scenario group is defined.

Consider the following deterministic model:

$$\begin{aligned} \max \quad & cx + ay \\ \text{s.t.} \quad & Ax + By = b \\ & x \in \{0, 1\}^n, y \geq 0, \end{aligned} \quad (1)$$

where c and a are the coefficient vectors of the objective function, b is the right-hand side vector, A and B are the constraint matrices, x and y are the 0–1 and continuous variables, respectively, and n is the number of 0–1 variables. The model will be extended

Figure 1. Annual price of pulpwood [US\$/ m^3], 1994–2003.

Figure 2. Scenario tree with 18 scenarios for Los Copihues case.

to incorporate the uncertainty of some of its parameters. We can now formulate the structured mixed 0–1 deterministic equivalent model (DEM) of the stochastic version of problem (1) to maximize the expected value of the objective function as follows:

$$\max Q_E = \sum_{\omega \in \Omega} w^\omega (c^\omega x^\omega + a^\omega y^\omega) \quad (2)$$

$$\text{s.t. } Ax^\omega + By^\omega = b^\omega, \quad \forall \omega \in \Omega; \quad (3)$$

$$x_t^\omega = x_t^{\omega'}, \quad \forall t \in \mathcal{T}, g \in \mathcal{G}^t, \omega, \omega' \in \Omega^g; \quad (4)$$

$$y_t^\omega = y_t^{\omega'}, \quad \forall t \in \mathcal{T}, g \in \mathcal{G}^t, \omega, \omega' \in \Omega^g; \quad (5)$$

$$x^\omega \in \{0, 1\}^n, y^\omega \geq 0, \quad \forall \omega \in \Omega. \quad (6)$$

We can observe that in the above model, the only constraints linking the various scenarios are the nonanticipativity constraints (4) and (5). It is unlikely (and we

verified this in practice) that a commercial optimization software package will be able to solve a large-scale real-life problem in a satisfactory manner. An efficient method for solving the $|\Omega|$ subproblems that arise when the constraints (4) and (5) are relaxed from the model but taken into account by the algorithm, is the branch-and-fix coordination (BFC) approach [31,32]. (See *Two-Stage Stochastic Integer Programming: A Brief Introduction* and *Stochastic Mixed-Integer Programming Algorithms: Beyond Benders' Decomposition*). The performance of the stochastic approach will be compared to the solution obtained from the average scenario.

Mixed 0–1 Model

The objective is to determine the optimal harvest and access road construction policy that will maximize expected net profit that is defined as the difference between the incomes (wood sale revenue) and the costs (wood harvest cost, production costs,

road construction cost, and wood transport cost) and satisfy the constraints for all scenarios. The decision to be taken for each scenario in the scenario tree and each time period, are the cells to be harvested, the roads to be built, the flow of good to be transported through the roads, and the demand of timber to be satisfied at each exit.

Formulation

$$\max Z = \sum_{\omega \in \Omega} \left(\sum_{s \in S} \sum_{t \in T} w^\omega R_s^{\omega,t} z_s^{t,\omega} - \sum_{h \in \mathcal{H}} \sum_{t \in T} w^\omega P_h^t A_h \delta_h^{t,\omega} - \sum_{o \in \mathcal{O}} \sum_{t \in T} w^\omega Q_o^t \right. \\ \left. \times \left(\sum_{h \in \mathcal{H}_o} a_h^t A_h \delta_h^{\omega,t} \right) - \sum_{(k,l) \in \mathcal{R}^P} \sum_{t \in T} w^\omega C_{k,l}^t \gamma_{k,l}^{t,\omega} - \sum_{(k,l) \in \mathcal{K}} \sum_{t \in T} w^\omega D_{k,l}^t f_{k,l}^{t,\omega} \right) \quad (7)$$

$$\sum_{h \in \mathcal{H}_o} a_h^t A_h \delta_h^{t,\omega} + \sum_{(k,o) \in \mathcal{K}} f_{k,o}^{t,\omega} - \sum_{(o,k) \in \mathcal{K}} f_{o,k}^{t,\omega} = 0, \quad \forall o \in \mathcal{O}, t \in T, \omega \in \Omega \quad (8)$$

$$\sum_{(k,j) \in \mathcal{K}} f_{k,j}^{t,\omega} - \sum_{(j,k) \in \mathcal{K}} f_{j,k}^{t,\omega} = 0, \quad \forall j \in \mathcal{J}, t \in T, \omega \in \Omega \quad (9)$$

$$z_s^{t,\omega} = \sum_{(k,s) \in \mathcal{K}} f_{k,s}^{t,\omega}, \quad \forall s \in S, t \in T, \omega \in \Omega \quad (10)$$

$$\underline{Z}^{t,\omega} \leq \sum_{s \in S} z_s^{t,\omega} \leq \bar{Z}^{t,\omega}, \quad \forall t \in T, \omega \in \Omega \quad (11)$$

$$f_{k,l}^{t,\omega} \leq U_{k,l}^t \sum_{1 \leq \tau \leq t} \gamma_{k,l}^{\tau,\omega}, \quad \forall (k,l) \in \mathcal{R}^P, t \in T, \omega \in \Omega \quad (12)$$

$$f_{k,l}^{t,\omega} \leq U_{k,l}^t, \quad \forall (k,l) \in \mathcal{R}^E, t \in T, \omega \in \Omega \quad (13)$$

$$\sum_{t \in T} \gamma_{k,l}^{t,\omega} \leq 1, \quad \forall (k,l) \in \mathcal{R}^P, \omega \in \Omega \quad (14)$$

$$\sum_{t \in T} \delta_h^{t,\omega} \leq 1, \quad \forall h \in \mathcal{H}, \omega \in \Omega \quad (15)$$

$$\delta_h^{t,\omega} = \delta_h^{t,\omega'} \quad \forall h \in \mathcal{H}, t \in T, g \in \mathcal{G}^t, \omega, \omega' \in \Omega^g \quad (16)$$

$$\gamma_{k,l}^{t,\omega} = \gamma_{k,l}^{t,\omega'} \quad \forall (k,l) \in \mathcal{R}^P, t \in T, g \in \mathcal{G}^t, \omega, \omega' \in \Omega^g \quad (17)$$

$$f_{k,l}^{t,\omega} = f_{k,l}^{t,\omega'} \quad \forall (k,l) \in \mathcal{R}^P, t \in T, g \in \mathcal{G}^t, \omega, \omega' \in \Omega^g \quad (18)$$

$$z_s^{t,\omega} = z_s^{t,\omega'} \quad \forall s \in S, t \in T, g \in \mathcal{G}^t, \omega, \omega' \in \Omega^g \quad (19)$$

$$f_{k,l}^{t,\omega}, z_s^{t,\omega} \geq 0, \quad \forall s \in S, (k,l) \in \mathcal{K}, t \in T, \omega \in \Omega \quad (20)$$

$$\delta_h^{t,\omega}, \gamma_{k,l}^{t,\omega} \in \{0, 1\}, \quad \forall h \in \mathcal{H}, (k,l) \in \mathcal{R}^P, t \in T, \omega \in \Omega \quad (21)$$

Variables

$\delta_h^{t,\omega} = 1$, if cell h is harvested in period t under scenario ω , and 0, otherwise.

$\gamma_{k,l}^{t,\omega} = 1$, if road in arc (k,l) is built in period t under scenario ω , and 0 otherwise.

$f_{k,l}^{t,\omega}$, flow of wood transported through arc (k,l) in period t under scenario ω [m^3].

$z_s^{t,\omega}$, demand of timber at exit s in period t under scenario ω [m^3].

The objective function of Equation (7) includes five terms representing the wood sale revenue, wood harvest cost, production costs at origin nodes, potential road construction cost, and wood transport cost. Constraints (8)–(10) are the flow balance equations at the origin nodes, intersection nodes and destination nodes, respectively. Constraint (11) is the wood demand bounds. Constraints (12) and (13) impose the flow capacity for the potential and existing roads, respectively. Constraint (14) ensures that each potential road is built at most once in the time horizon. Constraint (15) guarantees that a cell is harvested at most once in the time horizon. Constraints (16)–(17) and (18)–(19) impose the nonanticipativity principle for the 0–1 and continuous variables, respectively. Constraints (20) and (21) are the nonnegativity and integrality conditions for the variables.

Case Study

The forest property called Los Copihues, owned by the Chilean company Sociedad Forestal Millalemu has an area of 300 ha, divided into $|\mathcal{H}| = 25$ harvest cells based on company maps, with $|\mathcal{O}| = 9$ origins, $|\mathcal{J}| = 3$ junction nodes, $|\mathcal{S}| = 1$ exit node, $|\mathcal{R}^E| = 6$ existing roads, and $|\mathcal{R}^P| = 14$ potential roads. The planning horizon is divided into four time periods associated with years 2004, 2005, 2006, and 2007, respectively. The uncertainty of the problem is due to the unknown demand and timber sales prices. This uncertainty is represented in a tree with 18 scenarios as depicted in Fig. 2. For each node in the tree, the timber sales prices (\$) and the lower and upper bounds of the demand (10^3 m^3) are given.

The numerical experiments involve making comparisons between the performance of a solution adopted by a stochastic planner and a solution applied by a planner guided only by the average values of the uncertain parameters. In this experiment, it is assumed that the uncertain parameters evolve equiprobably. Given the large scale of the problem, we use the BFC approach in the search for the optimal solution. The results of the comparison are summarized in Table 1 for all scenarios. The average scenario-based

Table 1. Comparison of the Results

	Z_{AVSC}	Z_{BFC}	GAP %

tt	—	11942	—
Z_{IP}	—	5541451.0	—

solutions were obtained by simulating what happens in a given scenario, say, $\omega \in \Omega$, when applying the average scenario solution (AVSC). The headings are as follows: Z_{AVSC} , solution value of the average scenario approach for each scenario; Z_{BFC} , solution value of the BFC approach for each scenario; optimality GAP = $(Z_{\text{BFC}} - Z_{\text{AVSC}})/Z_{\text{AVSC}}$ (%); tt , total elapsed time (sec) for the solution value in all scenarios; Z_{IP} , expected solution value of the integer programming (IP) for the whole set of scenarios.

Notice that for the scenarios 10 through 18, the Z_{AVSC} column shows “infeasible.” This means that when the AVSC solution vector is substituted into these scenarios, a demand constraint is violated, thus rendering the solution mathematically infeasible.

It is of interest to analyze the possible significance of the previously discussed analysis to a forest manager. As was seen, the BFC approach led to better solutions than the deterministic approach under most scenarios, often by significant margins. But what was more significant, the deterministic approach could not find feasible solutions in multiple scenarios for all cases. The reason for these results is that in the deterministic case, where average expectations of market

conditions are taken, the possible fluctuations of future market conditions are not considered. This leads in multiple cases to decisions in the first periods that lead to conditions in future periods in relation to timber availability; this makes it difficult to react well under specific scenarios. In contrast, the BFC approach looks ahead at possible scenarios and protects itself against possible fluctuations. A forest manager might well want to consider these future possible fluctuations and protect his/her firm against them.

It is important to point out that a real planner can use the stochastic solution in a rolling time horizon, by using the decisions at stage 0 and re-running the model pushing it forward by one period after entering the realization of uncertain parameters each time. The decision to be made at the stage in a rolling horizon are the cells to be harvested, roads to be built, flow of goods to be transported through the roads, and demand of timber to be satisfied at each exit.

CONCLUSIONS

We have discussed the different forms in which uncertainty has been introduced into forest planning. We note that in general, forests have significant flexibility for harvesting, given the multiple options a planner has to harvest in a given moment. This is derived through selecting units to harvest as well as cutting patterns chosen to deliver different products. However, there are many situations where not considering uncertainty in an explicit form, working just with expected values may lead to significant losses in future periods. This happens when there is not much slack between supply and demand and decisions made early lock the planning process into patterns not easily reversible. We present one specific approach, BFC, to show how uncertainty can be expressed as a given set of scenarios of future prices. The nonanticipativity constraint is implicitly satisfied in the branching process. Computational results with a real forest data from the Chilean forest property Los Copihues show the advantages of expressing uncertainty explicitly through this approach.

UNDERSTANDING AND MANAGING VARIABILITY

HYUN-SOO AHN
Ross School of Business,
University of Michigan,
Ann Arbor, Michigan

Variability exists in almost all production and manufacturing systems. Demand and product mix may vary over time, as may the processing capacity of the system and the availability of raw materials and components. Even in an assembly line where all tasks are standardized, unexpected machine breakdowns or shortages of people and/or materials constrains output and disrupts the flow. Variability in demand or operation processes makes seamless alignment of demand and supply impossible and degrades system performance. In order to manage an efficient production/service system, it is essential for a manager to understand the causes and effects of variability. This article discusses the sources and types of variability, its effect on a production (or service) system, and some widely used managerial tools to mitigate the adverse effects of variability.

WHAT IS VARIABILITY?

Variability refers to the quality of nonuniformity of a class or entities in an attribute of interest [1,2]. For example, if all jobs take exactly 5 min to complete, then there is no variability in processing time. On the other hand, consider a case where 50% of jobs take exactly 4 min and the other 50% take 6 min. Although the *average* processing time is 5 min, the processing time for each individual job varies as some jobs may take longer (shorter) than the average. In manufacturing processes, many attributes are prone to vary even without specific root causes (e.g., processing times, physical (or chemical) specifications of an output, quality measures, job difficulty, and order size).

In some cases, it is possible to predict how something would vary as a function of environmental variables (such as time or temperature) or management decisions. For instance, it is possible to predict a daily pattern of electricity demand as a function of the time of the day and temperature. When there is a prescheduled setup or maintenance, any job in the queue may have to wait longer to be finished. In these cases, variation and its immediate effects can be predicted or controlled.

On the other hand, some variations can occur beyond our immediate control or prediction. This “random” (stochastic) variation does not have any recognizable pattern. For example, a disruption due to power outage or contamination cannot be predicted. Even in a manufacturing system that is seemingly under control, variations arise because of differences in operators, raw materials, and job difficulty. In most made-to-order systems, the times between customer orders are random, and this random fluctuation affects the workload of a manufacturing system. In a production line, no two outputs are entirely identical. These random variations arise by chance as a result of inherent randomness of the operation process, and are prevalent in manufacturing processes.

In many systems, both types of variability coexist. For example, the number of customers arriving to a restaurant varies in a way that is partially predictable (peaks during lunch or dinner) and partially unpredictable (the exact number of customers cannot be predicted with certainty). Likewise, a plant manager expects that there will be a number of machine outages, but cannot predict which machine will fail and when. Both types of variability degrade the performance of a manufacturing system: variability increases delay, increases work-in-process inventory, and reduces effective capacity and utilization. However, because of its unpredictability, the effects of random variation are more subtle and require an understanding of the relationship between the variability and

the flow of the good. This article primarily focuses on the effect of random variation.

SOURCES OF VARIABILITY IN MANUFACTURING PROCESSES

Some of the most common causes of random variability in manufacturing processes include machine breakdown, setups, rework, availability of raw material and operators, preventive maintenance, and environmental parameters such as temperature. In addition, heterogeneity in production resources (e.g., machine and operator) or job requirements cause variability as well. Virtually every operation has a certain degree of inherent pure randomness, which does not have any assignable causes.

In a manufacturing system where several operations are linked (e.g., flowshop or job shop), variability in an earlier operation is propagated to later operations since the departure (output) from an earlier operation becomes the arrival (input) to workstations performing later operations. On a bigger scale, the variability originated in an upstream member of the supply chain (e.g., disruption, quality uncertainties, and logistic network failure) affects downstream members of the supply chain. Consequently, the variability in one link of a supply chain propagates toward the entire chain. The propagation of variability is even more pronounced in an environment where the flow of all jobs is not identical (e.g., a job shop, a repair center). Even in the case that arrival times and processing times are predictable, the heterogeneity in job routing causes variability.

In both manufacturing and service systems, demand itself is a major source of variability. While some patterns of demand can be estimated with statistical models, no one can exactly predict the size and mix of the demand for end item(s). The number of orders received in a given period (say, day) fluctuates and so does the time between orders. Although it is possible to influence demand through operational and marketing levers, in general, there is always uncertainty about how many orders will arrive and when.

MEASURING VARIABILITY

When variation occurs and has no assignable root causes, it is difficult to predict the outcome of the variation in every single unit. Instead, we describe the underlying randomness of the system using a random variable and its statistical distribution. The value of a random variable is determined by the outcome of a random experiment. The range and likelihood of values that a random variable can attain are described through its probability distribution function. For any real-valued random variable, the cumulative distribution function $F(x)$ describes the probability that the random variable X does not exceed the value of x : $F(x) = P(X \leq x)$. If X is a discrete random variable, one can describe its probability distribution with the probability mass function, $P(X = x)$. If X is a continuous random variable, one can use the probability density function, defined as $f(x) = (dF(x)/dx)$, to characterize its probability distribution. For a given random variable, the statistical parameters (e.g., mean, variance, and skewness) are numerical measures that describe properties of a random variable and its distribution. The most widely used statistical parameter is the mean, which is used as a measure for the (probability-weighted) center of the distribution. For a discrete random variable, the mean of X (the expected value of X) is given by $E[X] = \sum_x xP(X = x)$. Analogously, the mean of a continuous random variable with density $f(\cdot)$ is given by $E[X] = \int xf(x)dx$. In the absence of theoretical mean, one can estimate it with the sample mean, $\bar{X}$: $\bar{X} = \frac{\sum_{i=1}^n x_i}{n}$ where n represents the number of observations in a sample.

Variability is closely related to statistical dispersion (or variation) from its mean. Statistical parameters that are commonly used to measure the statistical dispersions are the range, the variance (standard deviation), and the coefficient of variation. All assume the value of zero if there is no dispersion and become larger as a distribution becomes more spread out.

Range

The simplest measure of variation is the range, which is the difference between the

maximum value and minimum value. Although it is easy to compute, the range is very sensitive to the extreme values in the data (or the distribution). Furthermore, the range does not take into account the dispersion of the majority of the values and ignores distributional information.

Variance and Standard Deviation

The variance measures the average of the squared distances of the values from the mean of the distribution (denoted by μ) and is often denoted by σ^2 :

$$\sigma^2 = \text{Variance}[X] = E[(X - \mu)^2].$$

Since computing variance requires squaring the distances, it changes the unit of measurement to squared units. The standard deviation, which can be obtained by taking the square root of the variance, rescales the degree of dispersion to its original measurement unit. The standard deviation of a random variable X is simply the positive square root of the variance. When the population distribution is absent, one can use the sample variance, which is the best unbiased estimator for the population variance and can be computed as follows:

$$s^2 = \frac{\sum_i^n (x_i - \bar{X})^2}{n - 1}.$$

The sample standard deviation is obtained by taking the square root of the sample variance.

Coefficient of Variation

One important measure of variability is the coefficient of variation (CV), which is defined as the ratio of the standard deviation (σ) to the mean (μ), as follows:

$$\text{Coefficient of variation:} \\ \text{CV} = \frac{\text{Standard deviation}}{\text{Mean}} = \frac{\sigma}{\mu}.$$

In the absence of the population mean and standard deviation, one could estimate CV using the sample coefficient of variation with

Table 1. Examples of Coefficient of Variations for Commonly used Distributions

Random Variable	Mean	Standard Deviation	Coefficient of Variation
Uniform $[a, b]$	$\frac{a+b}{2}$	$\frac{(b-a)}{2\sqrt{3}}$	$\frac{b-a}{\sqrt{3}(b+a)}$
Exponential	$\frac{1}{\lambda}$	$\frac{1}{\lambda}$	1
Poisson	λ	$\sqrt{\lambda}$	$1/\sqrt{\lambda}$
Normal	μ	σ	$\frac{\sigma}{\mu}$

the sample standard deviation s and the sample mean $\bar{X}$.

The coefficient of variation has a number of nice properties. When there is no variation, the CV is naturally set to 0. Keeping the mean the same, the larger the CV value, the more dispersed (measured in units of standard deviation) the random variable is. For many widely used probability distributions, the CV can be characterized by the distribution parameters. Table 1 lists the mean, standard deviation, and coefficient of variation for some commonly used distributions.

The coefficient of variation measures the variation for the distribution compared to its mean and is useful when the *relative* variation is more important than the absolute variation to a decision maker. For instance, a standard deviation of 0.05 mm could represent a very high level of variation for the diameter of a vascular stent with a nominal thickness of 0.1 mm while a standard deviation of 5 mm could represent a very low level of variation for a large steel pipe. In this case, comparing variation using the standard deviation would be misleading. The CV describes the dispersion of the variable in a way that is independent of the variable's scale or dimension. However, the CV has a few discernible disadvantages. Obviously, the problem arises if the mean of a variable is zero, in which case the CV cannot be computed. Even if the mean of a variable is not zero, but the variable contains both positive and negative values and the mean is close to zero, then the CV can be misleading. However, because most quantities related to the flow of the good in the system (e.g., processing time) are positive quantities, the CV is a good indicator for describing the effects of variability for

the flow of the system. In fact, some of the most pronounced effects of variability, such as increased inventory, can be described as a function of the CV.

EFFECT OF VARIABILITY

In all manufacturing and service systems, variability inevitably arises and affects the performance of the system. Variability affects both the flow of a manufacturing system and the quality of output. Symptoms of variability include large inventory levels, long lead times, decreased utilization, and degradation of throughput.

To illustrate how variability affects the production system, consider a single workstation. Parts that arrive at the workstation can be interpreted in several ways: (i) they could be physical parts or subassemblies; (ii) they could be work orders; (iii) they could be broken machines (in case of a service station) or patients (in a hospital). If the part arrives at the workstation and sees no other part in the system, the part enters service. Otherwise, a line (queue) forms at the workstation.

Suppose that parts arrive at a rate of one every minute. In other words, the first part arrives at time zero, and at the beginning of each minute, a new part arrives. In this case, there is no variability in arrival time. If the workstation processes a part in exactly 1 min, each arriving part sees the machine idle upon arrival and enters service immediately. A queue does not form in this system. In any point in time, no more than one part is within or at the workstation. In addition, notice that demand perfectly matches processing capacity; thus the workstation is utilized 100% of the time. This is an example of a *perfectly balance deterministic production line* [1].

On the other hand, consider another workstation facing the same arriving stream. In this system, however, processing time is variable. With a 50% chance, it takes 1.25 min (75 s) to process a part. With a 50% chance, it takes 0.75 min (45 s) to process a part. Successive processing times are assumed independent. Notice that the average processing time is 1 min per part; thus, the utilization of this system is the same as that of the previous

example. However, the fluctuation in processing times results in inventory buildup. For instance, if the first part requires 1.25 min to process, the second part (which arrives exactly 1 min after the first part) cannot enter service upon arrival. Instead, it will be queued until the service for the first part is completed. Although the system looks balanced when judging by the average arrival and the service rate, occasionally parts will not arrive before the part in service is finished. How many parts will be in queue if this particular workstation operates long enough? It can be shown that, if it operates long enough, the average queue length grows to infinity. If the part requires physical space to store, no place on earth would be big enough to hold all the inventory.

The variability builds up a queue even when the overall utilization of the workstation is below 100%. For instance, in the preceding example, suppose that two consecutive parts arrive at the workstation with 66 s (1.1 min) apart. The utilization of this system, denoted by ρ , is:

$$\begin{aligned} \text{Utilization} = \rho &= \frac{\text{Arrival rate}}{\text{Process capacity}} \\ &= \frac{1}{\frac{\text{Average interarrival time}}{1}} \\ &= \frac{1}{1.1} \approx 90.91\%. \end{aligned}$$

The utilization of 90.91% indicates that, on average, the workstation does not work 100% of the time. Nonetheless, the variability in the process time allows a queue (inventory) to build up. For instance, if the processing time of the first part is 1.25 min, the second part (which arrives after 1 min) needs to wait for 15 s until the workstation clears the first job.

How does the variability in arrival time or processing time affect the time that a part spends in the queue and the inventory of the system? For the case with a single machine, an approximation formula, first developed by Kingman [3], describes the average time that a part waits in the queue. Let λ be the average arrival rate of parts to the workstation

and μ be the average rate of service completion. Thus, the average interarrival time is $1/\lambda$, the average processing time is $1/\mu$, and the utilization of the workstation is $\rho = \lambda/\mu$. From the definition, the coefficient of variation for the interarrival time (denoted by CV_a) and the coefficient of variation for the processing time (denoted by CV_s) are defined as follows:

$$CV_a = \frac{\text{Standard deviation of interarrival time}}{\text{Average interarrival time}}$$

and

$$CV_s = \frac{\text{Standard deviation of processing time}}{\text{Average processing time}}.$$

If interarrival time and/or processing time data are not available, the following approximation formulae (based on the central limit theorem for renewal processes) estimate CV_a and CV_s [4,5]:

$$CV_a = \frac{\text{Standard deviation of number of arrivals per unit time}}{\sqrt{\text{Average number of arrivals per unit time}}}$$

and $CV_s = \frac{\text{Standard deviation of number of jobs processed per unit time}}{\sqrt{\text{Average number of arrivals per unit time}}}.$

Kingman's formula states that the time that a job spends in the queue, denoted by W_q , can be approximated as follows:

$$W_q = \left(\frac{CV_a^2 + CV_s^2}{2} \right) \left(\frac{\rho}{1 - \rho} \right) \frac{1}{\mu}. \quad (1)$$

Note that the expression is valid only when $\lambda \leq \mu$. If $\lambda > \mu$, then in the long run, more parts will arrive than will be served, and thus the queue grows infinitely and so does the waiting time in the queue. Several insightful observations can be made from this simple expression:

- Unless the system is variability-free ($CV_a = CV_s = 0$), delay is an inevitable

phenomenon regardless of the utilization.

- Keeping everything else the same, the waiting time in the queue increases with the variability in interarrival and/or service times.
- The waiting time in the queue is a multiple of average processing time and increases with the utilization of the system. In particular, the waiting time will increase faster and faster as the utilization gets closer to 1. For instance, suppose that the waiting time in the queue for a given system is 1 when $\rho = 0.5$. Keeping everything else constant, the waiting time for the same system will be 1.5 if $\rho = 0.6$, 2.333 if $\rho = 0.7$, 4 if $\rho = 0.8$, 9 if $\rho = 0.9$, 19 if $\rho = 0.95$, and 99 if $\rho = 0.99$. In a highly utilized system, even a small increase in capacity (hence a small decrease in utilization) can significantly reduce waiting time.
- The total time that a part spends in the system (known as *cycle time*) W is the sum of the waiting time in the queue and its own processing time:

$$W = W_q + \text{Average processing time} \\ = \left(\frac{CV_a^2 + CV_s^2}{2} \right) \left(\frac{\rho}{1 - \rho} \right) \frac{1}{\mu} + \frac{1}{\mu}.$$

- The effect of the variability on inventory is Little's Law, which states that the average number of parts in the system, denoted by I , is equal to arrival rate times average cycle time: $I = \lambda W$ (see **Little's Law and Related Results** for details). Substituting the corresponding expression for the cycle time, the total inventory in the system is

$$I = \lambda W = \lambda \left[W_q + \frac{1}{\mu} \right] \\ = \left(\frac{CV_a^2 + CV_s^2}{2} \right) \left(\frac{\rho^2}{1 - \rho} \right) + \rho.$$

Hence, the inventory is proportional to the total time that a part spends in the system (cycle time), which increases in variability and utilization. Notice that,

if the system is highly variable and/or highly utilized, the vast majority of the cycle time is waiting in the queue. This is, in practice, why reducing cycle time often is considered equivalent to reducing inventory.

It can be shown that the expression is exact when the interarrival time is exponentially distributed (i.e., $CV_a = 1$). The formula for this special case (known as a $M/G/1$ queue) is formally known as the *Pollaczek-Khintchine* (P-K) formula [6,7]. If there are multiple workstations working in parallel, the waiting time in the queue W_q can again be approximated in terms of variability, utilization, and average processing time [8,9]. If there are m workstations in parallel, the utilization of the system will be modified to $\rho = (\text{Arrival rate}/\text{Process capacity}) = (\lambda/m\mu)$. Then, the waiting time in the queue can be approximated using the following formula:

$$W_q = \left(\frac{CV_a^2 + CV_s^2}{2} \right) \left(\frac{\rho^{\sqrt{2(m+1)}-1}}{1-\rho} \right) \frac{1}{m\mu}. \quad (2)$$

This approximation is solid as long as the number of workstations is not too large (e.g., $m \leq 20$ or so). In case there are many servers, another approximation by Halfin and Whitt [10] provides a good bound on the waiting time in the queue.

So far, we have seen that the variability in processing or arrival times results in an increase in waiting time and inventory. The above analysis assumes that there is no limit on the amount of inventory that can be queued (which we call *buffer*) in front of the workstation. In practice, physical or financial constraints may put a limit on this buffer. In such cases, the variability reduces the throughput, which is defined as the number of units finished in a given period. As Kingman's formula suggests, no inventory buffer is necessary in the perfectly balanced deterministic system since operation exactly meets demand, as no more than one part will be at any point in time. Recall the earlier example of a perfectly balanced deterministic production line where a new part arrives precisely at the beginning of each minute and the workstation processes each part in

exactly 1 min. In this system, a finished part leaves the system at the beginning of each minute, thus the long run average throughput is equal to the arrival rate, which is one part per minute (equivalently, 60 parts per hour). In a system with variability, this ideal throughput (equals to the arrival rate) can be achieved only when there is no limit on the buffer and the rate of service completion (μ) is greater than the arrival rate (λ).

What happens if there is a limit on the buffer size in a system that has variability? To illustrate this, suppose that the processing time is variable. The average production rate (μ) is still one part per minute, but the processing time for a part can be either less than or more than 1 min. Also, suppose that there is no buffer for inventory. Thus, if an arriving part sees that another part is in the workstation, it will be blocked from entering the system and leave. In this system, the variable processing time makes some parts arrive before the completion of the previous work, and thus will be blocked. Since some parts will be denied entry, the workstation will produce strictly fewer than 60 parts per hour. In the long run, the throughput of this system is smaller than the arrival rate. In addition, occasionally the workstation will be idle (because there is no part to work) and the utilization of the workstation drops. Although the case with no buffer seems extreme, the basic insights remain the same for any finite buffer: A portion of the arriving parts will be denied as the buffer becomes full, and, as a result, the throughput will be strictly lower than the arrival rate. Increasing the buffer will increase throughput and improve utilization as fewer parts will be denied entry. As the buffer grows, more parts can arrive independently from the status of the workstation, and the workstation can operate independently from arrival time fluctuations. The role of inventory buffer becomes more pronounced when operations are linked, where the output from one workstation becomes the input to another workstation. Inventory buffer between two linked operations isolates the effect of variability arising from one operation locally, and such decoupling helps both operations run smoothly.

Although the relationship between the inventory buffer and the throughput is intuitive, calculating the exact throughput for the case with general processing and interarrival time distributions is quite complicated. For a number of special cases (for instance, an $M/M/1/b$ queue or an Erlang loss systems, in both of which service and interarrival times are exponentially distributed), exact expressions are available [5,7]. For the general case, the approximation formula is available (see Ref. 11 for more details).

In most manufacturing systems, a part goes through multiple linked operations. When multiple operations are linked, departures from one workstation will be arrivals to other workstations. Therefore, the variability of the departure process at one workstation propagates to others. An example for this is a flow shop in which all parts sequentially go through a number of operations. Since the departure from workstation i becomes the arrival to workstation $i + 1$, the variability in the departure process from workstation i is indeed the variability of the arrival process to workstation $i + 1$. The exact dynamics on how variability propagates is quite complex and may depend on the utilization of the upstream workstation (workstation i). For instance, if the workstation i is lightly utilized (i.e., ρ_i is close to zero), then arriving parts rarely wait in the queue. In such a case, the variability in the departure process is almost identical to that in the arrival process. On the other hand, if workstation i is heavily utilized (i.e., ρ_i is close to 1), then it is almost always busy. Hence, the variability in the departure process resembles the processing time variability. One simple way to approximate the variability of the arrival process to workstation $i + 1$ is interpolating the variability of the arrival process to workstation i and the variability of processing times at workstation i with the following formula [2]:

$$\begin{aligned} CV_a^2(i+1) &= CV_{\text{departure}}^2(i) \\ &= \rho_i^2 CV_s^2(i) + (1 - \rho_i^2) CV_a^2(i). \end{aligned}$$

The formula implies that the effect of variability at one workstation propagates

throughout the system. The processing time variability in workstation 1 affects the arrival time variability in workstation 2, which then affects the arrival time variability at workstation 3, and so on. A corollary is that reducing the variability in an earlier stage of the operation is likely to have a greater impact than in a later stage.

Recall that, when the buffer size between two workstations is finite, the variability can decrease the throughput and the overall utilization of the system. Two events that degrade the throughput of the system are blocking (the part cannot join the buffer for the next workstation because it is full) and starving (the workstation becomes idle because there is no part to work on). Strategic placement of inventory can reduce these adverse events and increase both the throughput and the utilization. However, raising the inventory level is also detrimental to the system's performance in several ways. First, financial and/or physical resources are tied to the inventory until it is used. When the inventory level is large, it constrains the firm's resources (e.g., physical space, and working capital). Second, large inventory implies large cycle time. A longer cycle time has adverse effects on the quality of the product. Often, a long lead time is perceived as poor customer service resulting from the firm's inability to react to consumer orders in a timely manner. In addition, a longer cycle time (large inventory) makes detecting and responding to quality problems difficult, as many parts need to be worked through ahead of a defective part.

Variability affects the flow of units in the system, along with the quality of the units. In fact, the root cause of the quality problem is variability in operating processes. The variation due to inherent randomness in the operation causes output and quality to vary. Variations in physical dimensions or electronic specifications of the components affect the quality of finished goods. Since defective units either need to be reworked or scrapped, defects are not only costly to the firm but also affect the flow of the system because more units are needed to be created to ship a given number of good units. Suppose that 5% of produced parts are defective and need to be

scrapped. Accounting for possible defects, on average about 105.3 parts need to be processed in order to produce a batch of 100 good parts. The increased demand will increase the utilization of the system and affect the inventory and cycle time. In order to increase throughput without significantly alerting the inventory and cycle time, process improvements that reduce operational variability are necessary. In fact, high quality is one of the primary reasons behind the success of the Just-In-Time production system, popularized by Toyota [12].

MANAGING VARIABILITY

Variability affects the flow and the quality of the goods produced. To insulate the manufacturing process from variability, managers deploy a variety of operational tools to mitigate the effect of variability.

Inventory Buffering

A passive approach toward managing variability is to hold inventory. As illustrated earlier, inventory decouples each operation and isolates the effect of variability. Thus, inventory can alleviate some of the symptoms of variability in system: loss of utilization and throughput, blocking, and starving. Inventory placed between operations helps each workstation operate independently from its neighboring stations. By insulating each operation from its neighbors, the system is capable of producing output at a consistently high throughput rate. Strategic placement of inventory can also buffer the manufacturing operation from external variability (originated from suppliers or demand) as well. Holding safety stock of finished goods buffers the manufacturing operation from demand variability. Likewise, safety stock of key components isolates manufacturing operations from the variability arising from a supplier (e.g., lead time variability and supplier disruption). In the case where demand variability is predictable (seasonal demand or periodic discount), inventory will buffer the difference between capacity and demand.

It should be noted, however, that a buildup of inventory allows managers to work around the problems associated with variability by simply hiding them. In fact, a large inventory hides underlying problems in manufacturing operations, which can be recognized and resolved otherwise. Furthermore, as Little's law suggests, a large inventory means a longer cycle time, which has several adverse effects as well. The benefits of using an inventory buffer must be weighed against its costs.

Time and Capacity Buffering

When an inventory buffer is not feasible, the firm can use time or capacity as a buffer to mitigate the effects of variability. Adding slack time between two tasks ensures that a sequence of tasks with variable processing times is completed. Dynamic lead time quotation that takes into account of congestion in the system lets consumer know when they will receive the good (although excessively long lead times may turn away some customers). Adding temporary capacity (e.g., a floater in a manufacturing line) or allowing overbooking provides a capacity buffer against variable demand. The use of these buffers, once again, hides problems associated with variability, but does not eliminate them. In addition, deploying these buffers can be quite costly. The firm must weigh the benefits of the buffer against its direct and indirect costs associated with the buffer.

Variability Pooling

Another way to mitigate the harmful effect of variability is to pool multiple resources (or demand streams). Pooling allows the resource to be utilized more effectively, as it balances the workload evenly among production resources. In addition, pooling independent sources of variability can lead to a reduction in variability (measured by coefficient of variations).

One form of variability pooling is *queue sharing*, in which multiple workstations share a single queue. Instead of an individual queue for each workstation (hence, each workstation is dedicated to work on the parts

arriving to its own queue only), one could form a single queue shared by a number of like workstations. Pooling enables production resources to be utilized more effectively, as it prevents one workstation being idle while queues build up at other workstations, and thus it reduces cycle time. For example, consider identical workstations (with the capacity of $\mu = 1$), each having parts that arrive at the rate of $\lambda = 0.9$. (Compare this system with the pooled system, which combines the two arrival streams.) Notice that the utilization of the system remains the same since both arrival and processing rates are doubled. Suppose that the variability in both the interarrival time and processing time remains unchanged. Then, it can be shown by comparing Equations (1) and (2) that the time that a part waits in the queue of the pooled system is only 47.5% of that of the system with two separate queues. By pooling multiple workstations, the flow of the system becomes less affected by the status of any particular workstation: Even if one of the workstations experiences a longer than expected processing time, the parts move through the system. This type of pooling has been successfully implemented in many manufacturing and service organizations including banks, call centers, and semiconductor fabs [2].

Variability pooling can also be used at the supply chain level. Instead of placing safety stock at each demand point (e.g., retailer and salesperson), one can aggregate the demand and place safety stock at the distribution center level. By pooling demand from multiple sources, the total demand variability is reduced, thus the same service level can be achieved with a smaller amount of safety stock. Some companies reverse the operational sequence (e.g., knitting before dyeing, stocking a generic inventory of printer assemblies, and putting the power supply which is specific to the region it is shipped, etc.) in order to capitalize the pooling effect [13].

Operational Flexibility

Adding *flexible workstations* or *cross-training workers* can also reduce the effect of variability. When there is no job to

work on, cross-trained workers can aid the congestions at other workstations. This will reduce the starvation and blockage due to variability, and increase the throughput of the system. Examples include bucket-brigade teams used in order-picking centers [14,15] and the use of computed numerically controlled (CNC) or five-axis machine centers used on the shop floor [16]. The concept of flexibility can also be implemented at the supply chain level. The use of a back-up supplier or dual sourcing mitigates the variability originating from a supplier (e.g., disruption). In many instances, addition of limited flexibility (i.e., each plant builds only a few products) is enough to capture much of the benefits from flexibility [17].

Process Improvement

Some modern management practices call for reducing the variability itself instead of working around it. Variability reduction through continuous process improvement is a prerequisite for the success of the *Just-in-Time* (JIT) and *lean* manufacturing systems. The core of these approaches is to improve the production process, eliminating the root causes of operational variability, and to improve efficiency (measured by utilization and throughput), responsiveness (measured by lead time), and quality. For instance, Toyota reduced processing time variability through setup reductions and process standardization. Toyota also improved the quality of its finished products through total quality management (TQM), error proofing, and collaboration with vendors. It should be noted that the reduced cycle time and work in process are the outcome of successful implementation of these approaches, not the reason behind the success. One of the most common misunderstandings about the JIT system is that lowering the inventory itself is a reason behind success. Without reducing operational variability, simply reducing the inventory does not increase the throughput of the system. Once the variability is reduced with process improvement, the amount of inventory required to maintain a given

throughput level is decreased and the cycle time is reduced.

Design for Manufacture

The root causes of variations in the manufacturing process are often attributed to poor product or operation designs. In such case, addressing potential failure points at the design stage could reduce variability. *Design for manufacture* implements this concept [18]. Eliminating non-value-added steps in the manufacturing process (or dropping nonvalue-added parts) will improve the flow time and product quality, along with reducing defects. One example of the design for manufacture is to simplify product or process design to reduce operational complexity. For higher volume parts, producing the parts by casting or extruding can reduce processing time. Standardizing or fool-proofing the manufacturing process is another example of design for manufacture. Instead of using different screws, using a uniform screw size reduces the both assembly time and the chance of assembly errors. Adding dowel pins to a part will help to orient the part easily. Using interchangeable parts or modules helps to reduce variability, as well as to standardize the operation. All of these efforts help to streamline and standardize the manufacturing operations.

Demand Shaping

The variability of consumer demand can be reduced by employing smart pricing or assortment strategies [19]. One example is the use of everyday low pricing (EDLP); popularized by Walmart. Constant pricing eliminates the variations of demand attributed to the changes in price. As a result, the retailer faces a less variable demand stream. Offering a discount to predesigned bundles (e.g., preconfigured computer) is another example of demand shaping. By inducing customers to purchase a certain type of product (as opposed to each customer configuring his/her own product), the firm can make demand process more predictable. Demand shaping can also be applied in service industries. Offering

discounts during off-peak hours (e.g., early bird special, happy hour, weekend rental discount) reduces demand fluctuations and levels out the utilization of the system [20]. In the same spirit, appointment or reservation systems improve the ability to predict future demand. Although appointment or reservation systems alone may not necessarily reduce the underlying variability of the demand process, the improved visibility on future demand enables matching supply with demand better.

UNIFORMIZATION IN MARKOV DECISION PROCESSES

OGUZHAN ALAGOZ

Department of Industrial and
Systems Engineering, University
of Wisconsin-Madison, Madison,
Wisconsin

Most Markov decision process (MDP) models consider problems with decisions occurring at discrete time points. On the other hand, there are several real-life applications, particularly in queueing systems, in which the decision maker chooses actions at random times over a continuous-time interval. Such problems can be modeled using continuous-time models. Semi-Markov decision processes (SMDPs) (see *Semi-Markov Decision Processes*), a class of continuous-time models, generalize discrete-time Markov decision processes (DTMDPs) by allowing state changes to occur randomly over continuous time and letting or requiring decisions to be taken whenever the system state changes [1,2]. In SMDPs, the stochastic process defined by the state transitions follows a discrete-time Markov chain while the time between each transition is drawn from a general distribution, independent of transitions [1,3].

Continuous-time Markov decision processes (CTMDPs) constitute a special type of SMDPs in which the transition times between decisions are exponentially distributed and actions are taken at every transition [2]. Uniformization, as a tool, is used to convert a CTMDP into an equivalent DTMDP. Although uniformization has been used to analyze continuous-time Markov processes for a long time [4–7], Serfozo [8] formalized the use of uniformization in the context of countable-state CTMDPs.

In this article, we will describe uniformization in CTMDPs. Although we consider CTMDPs with stationary transition probabilities and reward functions, bounded reward functions, and finite state and action

spaces, the results can be easily extended to CTMDPs with countable state and action spaces as well as to more general spaces with appropriate measurability conditions [8]. While we focus on uniformization only for infinite-horizon CTMDPs with total expected discounted reward criterion, uniformization can also be utilized in CTMDPs with average reward criterion [2]. Assuming a unichain transition probability matrix for every stationary policy, the transformation and modeling scheme for solving CTMDPs with average reward criterion is identical to those described in this article except for the computation of the reward function. The results apply to multichain cases as well, with slight modifications. More information on uniformization in CTMDPs with average reward criterion is available elsewhere [2].

The remainder of this article is organized as follows: we next summarize how uniformization is used to convert a continuous-time Markov chain (CTMC) into an equivalent discrete-time Markov chain. Then, we describe the use of uniformization in CTMDPs. Finally, we present two examples for uniformization.

UNIFORMIZATION IN CONTINUOUS-TIME MARKOV CHAINS

CTMCs are formally defined as follows [9] (see the section titled “Continuous-Time Markov Chains (CTMCs)” in this encyclopedia): a continuous-time stochastic process $\{X(t), t \geq 0\}$ is a CTMC if for all $s, t \geq 0$ and nonnegative integers $i, j, x(u)$ where $0 \leq u < t$,

$$\begin{aligned} P\{X(t+s) = j | X(t) = i, X(u) = x(u), 0 \leq u < t\} \\ = P\{X(t+s) = j | X(t) = i\}. \end{aligned}$$

A CTMC is a stochastic process with the Markovian property; that is, the conditional distribution $P(X(s+t)|X(u))$ of the future state $X(t+s)$ is independent of the past states $X(u), 0 \leq u < t$ and only depends on

the current state $X(t)$ (see **Definition and Examples of Continuous-Time Markov Chains**).

Consider a CTMC in which the time to make a transition from its current state to a different state is exponentially distributed with β for all states. Let $P_{ij}(t)$ denote the probability of being in state j at time t starting from state i at time 0. Note that the number of transitions by time t , $\{N(t), t \geq 0\}$ is a Poisson process with rate β [9]. Therefore, $P_{ij}(t)$ can be recasted by conditioning on the number of transitions by time t as follows:

$$\begin{aligned} P_{ij}(t) &= P\{X(t) = j | X(0) = i\} \\ &= \sum_{n=0}^{\infty} P\{X(t) = j | X(0) = i, N(t) = n\} \\ &\quad \times P(N(t) = n | X(0) = i) \\ &= \sum_{n=0}^{\infty} P\{X(t) = j | X(0) = i, N(t) = n\} \\ &\quad \times e^{-\beta t} \frac{(\beta t)^n}{n!} \\ &= \sum_{n=0}^{\infty} P_{ij}^n e^{-\beta t} \frac{(\beta t)^n}{n!}, \end{aligned} \quad (1)$$

where P_{ij}^n represents the n -step stationary transition probability of an equivalent discrete-time Markov chain with transition probabilities P_{ij} . That is,

$$P\{X(t) = j | X(0) = i, N(t) = n\} = P_{ij}^n. \quad (2)$$

Equation (1) follows from the assumption that the time spent in every state is exponentially distributed with rate (β) . More specifically, the probability of moving from i to j in n transitions is equal to the probability of moving from i to j by time t since moving in n steps does not give any information on which states were visited due to identical sojourn times. Therefore, Equation (2) can be applied only if all states have identical sojourn time distributions. In order to convert a CTMC with different transition rates into a discrete-time Markov chain we use *uniformization*.

Suppose the mean sojourn time at each state is $1/\beta_i$ and there exists a finite constant β such that $\beta_i \leq \beta$, for all i . According to the new scheme, we assign the same transition

rate β to all states i , where the transition process is divided into two: the “fictitious” transitions to the state itself and the transitions to the other states. To match the actual process, we will have the process remain in each state for an exponential amount of time with rate β and the new transition probabilities will be defined as

$$\tilde{P}_{ij} = \begin{cases} 1 - \frac{\beta_i}{\beta}, & j = i, \\ \frac{\beta_i}{\beta} P_{ij}, & j \neq i. \end{cases}$$

Applying the new transition probabilities to Equation (1), we obtain

$$P_{ij}(t) = \sum_{n=0}^{\infty} (\tilde{P}_{ij})^n e^{-\beta t} \frac{(\beta t)^n}{n!}.$$

Figure 1 shows the schematic of a simple uniformization example. In summary, uniformization enabled us to convert a CTMC with state-dependent out-of-state transition rates into an analytically equivalent CTMC with uniform transition rates. This new system could be treated as a discrete-time Markov chain for the purposes of analysis [9].

UNIFORMIZATION IN CONTINUOUS-TIME MARKOV DECISION PROCESSES

In this section, we describe the uniformization process in CTMDPs. We start with the simpler case, where the transition rates are uniform and then extend this to the more general form, where the transition rates are state-and-action-dependent.

Uniform Transition Rates

Consider an infinite-horizon discounted CTMDP with the following reward (cost) function:

$$\lim_{n \rightarrow \infty} E_s \left[\int_0^{t_n} e^{-\alpha t} g(s(t), a(t)) dt \right],$$

where t_n represents the time of n th transition, $n = \{1, \dots, \infty\}$; α is the continuous-time discounting factor, $\alpha > 0$; $g(s(t), a(t))$ is the reward obtained when action $a(t)$ is selected at state $s(t)$. If we let s_n and a_n denote

Figure 1. An illustrative example for the uniformization of a CTMC through the use of fictitious self-transitions.

the state and the action selected at time t_n , respectively, then $s(t) = s_n$ and $a(t) = a_n$ hold where $t_n \leq t < t_{n+1}$.

Suppose $g(s(t), a(t))$ consists of two parts: $K(s(t), a(t))$, the lump reward obtained when a new state and action pair is observed and $C(s(t), a(t))$, the continuous reward accumulated if the state was $s(t)$ and action $a(t)$ was taken in the last decision epoch. The state of a CTMDP does not change between decision epochs, therefore, the value of a given policy π for a CTMDP, v_α^π , that is, the total expected discounted reward over the infinite horizon for π is calculated as follows:

$$v_\alpha^\pi = E_s^\pi \left[\sum_{n=0}^{\infty} e^{-\alpha t_n} \left(K(s_n, a_n) + \int_{t_n}^{t_{n+1}} e^{-\alpha(t-t_n)} C(s_n, a_n) dt \right) \right]. \quad (3)$$

Let $\tau_{n+1} = t_{n+1} - t_n$ ($\tau_0 = t_0 = 0$) denote the time the process remains in s_n , which is distributed exponentially with parameter β for all states. Then, we can rewrite Equation (3) as follows:

$$v_\alpha^\pi = E_s^\pi \left[\sum_{n=0}^{\infty} e^{-\alpha t_n} K(s_n, a_n) \right]$$

$$\begin{aligned} & + E_s^\pi \left[\sum_{n=0}^{\infty} e^{-\alpha t_n} C(s_n, a_n) \cdot \int_0^{\tau_{n+1}} e^{-\alpha t} dt \right] \\ & = E_s^\pi \left[\sum_{n=0}^{\infty} e^{-\alpha(\tau_1 + \dots + \tau_n)} K(s_n, a_n) \right] \\ & + E_s^\pi \left[\sum_{n=0}^{\infty} e^{-\alpha(\tau_1 + \dots + \tau_n)} \frac{1}{\alpha} \right. \\ & \quad \left. \times (1 - e^{-\alpha \tau_{n+1}}) C(s_n, a_n) \right] \\ & = \sum_{n=0}^{\infty} E_s^\pi [K(s_n, a_n)] (E_s^\pi [e^{-\alpha \tau_1}])^n \\ & + \sum_{n=0}^{\infty} E_s^\pi [C(s_n, a_n)] \frac{1}{\alpha} (E_s^\pi [e^{-\alpha \tau_1}])^n \\ & \quad \times (1 - E_s^\pi [e^{-\alpha \tau_1}]), \end{aligned} \quad (4)$$

where Equation (4) follows from the assumption that $\{\tau_1, \tau_2, \dots, \tau_{n+1}\}$ are independent and identically distributed with exponential distribution and s_n is independent of $\tau_1, \tau_2, \dots, \tau_{n+1}$. Evaluating the expectation of the exponential,

$$E_s^\pi [e^{-\alpha \tau_1}] = \int_0^{\infty} e^{-\alpha t} \beta e^{-\beta t} dt = \frac{\beta}{\alpha + \beta} := \lambda,$$

and rewriting this equation with the λ substituted in Equation (4), we obtain

$$\begin{aligned}
v_\alpha^\pi &= E_s^\pi \left[\sum_{n=0}^{\infty} \lambda^n \left(K(s_n, a_n) + \frac{C(s_n, a_n)}{\alpha + \beta} \right) \right] \\
&= E_s^\pi \left[\sum_{n=0}^{\infty} \lambda^n r(s_n, a_n) \right],
\end{aligned}$$

which has the same form as an equivalent DTMDP if we redefine $[K(s_n, a_n) + C(s_n, a_n)/(\alpha + \beta)] = r(s_n, a_n)$ as the total expected discounted reward between two decision epochs for the (s_n, a_n) pair. Note that this was achieved since the sojourn times at each state are assumed to be independent and identically distributed with exponential distribution.

To summarize, a CTMDP with the reward function

$$\lim_{n \rightarrow \infty} E_s \left[\int_0^{t_n} e^{-\alpha t} g(s(t), a(t)) dt \right],$$

and a transition rate β for all states and actions is equivalent to a DTMDP with the discount factor

$$\lambda = \frac{\beta}{\alpha + \beta},$$

and the total expected discounted reward between two decision epochs is given by

$$r(s, a) = \left[K(s, a) + \frac{C(s, a)}{\alpha + \beta} \right], \quad (5)$$

where the reward functions K and C are defined as above. Let $P(j|s, a)$ represent the probability that the state at the next decision epoch will be j , given that the state is s and action a is taken at the last decision epoch. Then, the Bellman equations can be rewritten as

$$v(s) = \max_{a \in A_s} \left\{ r(s, a) + \lambda \sum_{j \in S} P(j|s, a) v(j) \right\},$$

and be solved as a DTMDP, where A_s and $v(j)$ represent the set of available actions at state s and the optimal total expected discounted reward that can be obtained when the process starts in state j , respectively.

Nonuniform Transition Rates

A major limiting assumption for the above result is the assumption of identical transition rates across all states and actions. In this section, we show that by *allowing fictitious transitions from a state to itself* as in the previous section, we can extend the results for CTMDPs with uniform transition rates to those with nonuniform transition rates.

Let $\beta(s, a)$ denote the transition rate out of state s when action a is taken and β represent a uniform transition rate satisfying $\beta(s, a) \leq \beta$, $\forall s \in S$ and $a \in A_s$, where A_s represents the action space for state s . We can then modify the transition probabilities as

$$\tilde{P}(j|s, a) = \begin{cases} 1 - \frac{\beta(s, a)}{\beta}, & j = s; \\ \frac{\beta(s, a)}{\beta} P(j|s, a), & j \neq s. \end{cases} \quad (6)$$

By creating fictitious transitions, we are creating a stochastically equivalent process in which the transitions occur more often. As an example, when the process is in state s , it will leave s at a faster rate β but will return to the same state with $1 - \beta(s, a)/\beta$ probability. Probabilistically, the new process will move to another state at the same rate as in the original one. As a result of the uniformization of the nonidentical transition rates, we can use the results for CTMDPs with uniform transition rates.

To summarize, we can analyze a CTMDP with exponential transition rates $\beta(s, a)$, transition probabilities $P(j|s, a)$, and a reward function of

$$\lim_{N \rightarrow \infty} E_s \left[\int_0^{t_N} e^{-\alpha t} g(s(t), a(t)) dt \right],$$

by converting it into an equivalent CTMDP with the discount factor $\lambda = \frac{\beta}{\alpha + \beta}$, where $\beta(s, a) \leq \beta$, $\forall s \in S$, $\forall a \in A_s$ and the transition probabilities are given by Equation (6). The total expected discounted reward between two decision epochs is given by Equation (5). The optimality equation is then written as

$$v(s) = \max_{a \in A_s} \left\{ K(s, a) + \frac{C(s, a)}{\alpha + \beta} \right\}$$

$$+ \frac{\beta}{\alpha + \beta} \sum_{j \in S} \tilde{P}(j|s, a) v(j) \Big\} \quad (7)$$

$$= \max_{a \in A_s} \left\{ r(s, a) + \lambda \sum_{j \in S} \tilde{P}(j|s, a) v(j) \right\} \quad (8)$$

and can be analyzed as a DTMDP. It can easily be shown [10] that after several simple algebraic manipulations, Equations (7) and (8) can also be presented as follows:

$$v(s) = \frac{1}{\alpha + \beta} \max_{a \in A_s} \left\{ (\alpha + \beta) K(s, a) + C(s, a) + (\beta - \beta(s, a)) v(s) + \beta(s, a) \sum_{j \in S} P(j|s, a) v(j) \right\}.$$

The optimality equations given by Equation (8) provide a compact form that is very similar to the conventional optimality equations for DTMDPs and therefore, are easier to comprehend.

EXAMPLES

In this section, we present two simple examples from queueing systems to illustrate the use of uniformization in continuous-time Markov models. More examples for the application of uniformization to CTMDPs are available elsewhere [2,10,11].

Meeting the Professor. Students come in randomly during Professor Smith's office hours and on some occasions, they find the professor busy with other students, in which case they leave and return later. The interarrival times of the students are independent and identically distributed exponentially with rate ω , and it takes exponential amount of time with rate μ for Professor Smith to finish with a student. A student arrives at the office and finds the professor busy with another student. We compute the probability that the professor will be available if the student comes back at time t .

We model the process as a birth and death process, where states 0 and 1 represent

when the professor is available and busy with another student, respectively. We can solve a set of differential equations to calculate the probability in the question. However, we will solve this problem using uniformization. Note that this problem is essentially an M/M/1/1 queue. The reader can refer to Ref. 9 for an analysis of the model to derive the probability in question.

The process has the following parameters:

$$\beta_0 = \omega, \beta_1 = \mu, \text{ and } P_{01} = P_{10} = 1.$$

By defining $\beta = \omega + \mu$, we can uniformize the CTMC to obtain

$$\begin{aligned} \tilde{P}_{00} &= \frac{\mu}{\omega + \mu} = 1 - \tilde{P}_{01}, \\ \tilde{P}_{10} &= \frac{\mu}{\omega + \mu} = 1 - \tilde{P}_{11}. \end{aligned}$$

This creates a new transition matrix with identical entries in a column:

$$\tilde{P}_{ij} = \begin{pmatrix} \frac{\mu}{\omega + \mu} & \frac{\omega}{\omega + \mu} \\ \frac{\mu}{\omega + \mu} & \frac{\omega}{\omega + \mu} \end{pmatrix} = \tilde{P}_{ij}^n$$

$$i, j = \{0, 1\} \quad n = 1, 2, \dots$$

Hence, using the uniformization for CTMCs,

$$\begin{aligned} P_{11}(t) &= \sum_{n=0}^{\infty} \tilde{P}_{11}^n e^{-(\omega + \mu)t} \frac{[(\omega + \mu)t]^n}{n!} \\ &= e^{-(\omega + \mu)t} + \sum_{n=1}^{\infty} \left(\frac{\omega}{\omega + \mu} \right) \\ &\quad \times e^{-(\omega + \mu)t} \frac{[(\omega + \mu)t]^n}{n!} \\ &= e^{-(\omega + \mu)t} + [1 - e^{-(\omega + \mu)t}] \frac{\omega}{\omega + \mu} \\ &= \frac{\omega}{\omega + \mu} + \frac{\mu}{\omega + \mu} e^{-(\omega + \mu)t}. \end{aligned}$$

The required probability is then

$$P_{10}(t) = 1 - P_{11}(t) = \frac{\mu}{\omega + \mu} [1 - e^{-(\omega + \mu)t}].$$

Professor's Dilemma. Consider a slightly modified version of the above example. Namely, we will now model the professor's

decision on how fast he should answer a student's questions.

Suppose, the professor has only three chairs in the office and students coming to the office hours get in only if there is a vacant seat in the office. Every time a student comes in, the professor sets his pace in answering questions so that he can be fair to all that are waiting. His pace in terms of time he expects to spend with a student, is distributed exponentially with a mean that is in $[1/\bar{\mu}, 1/\mu]$ interval. Each time a student comes in, the professor will accrue a reward of $U(s, \mu)$, the immediate utility he gets when the total number of students in the office is s and he chooses his pace as μ . The utility depends on the number of people waiting, as well as the pace reflecting the quality of time he expects to spend with the students. On the other hand, he accrues a utility of $u(s, \mu)$ while he is answering the student's questions and this is continuously discounted at rate α reflecting the fact that the more time he spends with a student, the less he can spend with others. We will write the optimality equations for Professor's pace decision problem.

We define the state space $S = \{0, 1, 2, 3\}$, representing the number of students that are in the office. The transition rates are

$$\beta(s, \mu) = \begin{cases} \omega, & s = 0; \\ \omega + \mu, & s = 1, 2; \\ \mu, & s = 3. \end{cases}$$

The maximum possible transition rate is $\beta = \omega + \bar{\mu}$. The new transition probability matrix for a given μ is as follows:

$$\tilde{P} = \begin{pmatrix} \frac{\bar{\mu}}{\omega + \bar{\mu}} & \frac{\omega}{\omega + \bar{\mu}} & 0 & 0 \\ \frac{\mu}{\omega + \bar{\mu}} & \frac{\bar{\mu} - \mu}{\omega + \bar{\mu}} & \frac{\omega}{\omega + \bar{\mu}} & 0 \\ 0 & \frac{\mu}{\omega + \bar{\mu}} & \frac{\bar{\mu} - \mu}{\omega + \bar{\mu}} & \frac{\omega}{\omega + \bar{\mu}} \\ 0 & 0 & \frac{\mu}{\omega + \bar{\mu}} & \frac{\omega}{\omega + \bar{\mu}} \end{pmatrix},$$

where (s, j) entry of $\tilde{P}$ represents $\tilde{P}(j|s, a = \mu)$. Uniformizing the decision process via using β and the above transition matrix followed by application of Equation (7) leads us to the optimality equations given by

$$v(s) = \max_{\mu \in [\underline{\mu}, \bar{\mu}]} \left\{ U(s, \mu) + \frac{u(s, \mu)}{\alpha + \beta} + \frac{\beta}{\alpha + \beta} \sum_{j \in S} \tilde{P}(j|s, \mu) v(j) \right\}.$$

As discussed in the previous section, the above equations could be converted to the form of Equation (8), and therefore can be solved using conventional DTMDP solution techniques such as value iteration, policy iteration, or linear programming (see **Total Expected Discounted Reward MDPs: Value Iteration Algorithm** and **Total Expected Discounted Reward MDPs: Policy Iteration Algorithm**).

OVERVIEW AND NEED

Today's operational forces are experiencing an explosion in both the need and availability of small, agile Unmanned Air System (UAS) platforms to support small unit operations in urban and mountainous settings. However, there are a number of factors that limit the capability of these small platforms in these environments. First, small UAS are usually equipped with limited, small video payloads, are generally restricted to line-of-sight communication, and have a one-vehicle/multi-operator operational architecture, which can restrict the timely exchange of information. In addition, existing small UAS platforms do not readily lend themselves to flight within the complex, highly variable *aerodynamic* environments associated with the mission areas defined above. Because of this factor alone, it is important that a detailed understanding of the unsteady airflow environment and its impact on vehicle performance be developed to reduce the high risk of failure associated with these UAS missions. Traditionally, a combination of controlled wind tunnel experiments, field trials, and computer modeling would be used to underpin UAS technology development programs. However, experimental facilities are

not yet available that replicate the primary physics of the urban (or other complex environment) conditions on a scaled level and field trials are often prohibitively expensive or logistically impossible. As such, there is a need for accurate, high-fidelity air flow models to help reduce the risk of failure of UAS surveillance and engagement missions.

Urban aerodynamics, for example, is complicated due to the existence of complex interactions between terrain geometry, physical conditions, and varying meteorology. High-fidelity computational fluid dynamics (CFD) models exist, which capture these interactions as well as the primary first-order effects of turbulence, heat transfer, and buoyancy. The effects of turbulence, heat transfer, and buoyancy must be given special attention to accurately characterize airflow in an urban environment. Using sufficient resolution, these large eddy simulation (LES) models provide a viable means to characterize urban environments within the urban canopy layer. The authors have successfully integrated these extant CFD models and their real-time effects on embedded UAS within a synthetic modeling environment. With the understanding that aerodynamic effects are not the *only* driver of mission success, the authors have incorporated urban-terrain UAS aerodynamic data and a UAS vehicle dynamics model (which includes the systems, autopilot, algorithms, etc.) as well into a real-time, comprehensive, physics-based simulation tool for the study of vehicle–environment interactions (Fig. 1) and their impact on mission success. With further development, this tool could improve our understanding of UAS performance in complex environments, providing unique capability and flexibility to the small UAS systems engineering and operational communities.

Owing to its comprehensiveness and physics-based underpinnings, such a tool is capable of supporting the entire systems engineering life-cycle for UAS development and deployment. Because it is modular in design, individual components may be

Figure 1. UAV M&S environment key components.

exchanged without fundamentally changing the overall modeling and simulation (M&S) architecture. Communications modeling and mission-level autonomy logic add to its utility as a means of exploring design and operational questions from an end-to-end perspective. With tight development and delivery schedules, not much room exists for systems engineering rigor, quantitative analysis of alternatives, or strong test and evaluation of concepts and designs for to-be fielded systems. Synthetic environments such as the one described here enable design engineers and analysts to address these needs without sacrificing the agility, which is a feature in current UAS acquisition processes.

CHARACTERIZATION OF THE ENVIRONMENT

Urban Aerodynamics

Even when considering flows around simple geometric shapes where turbulence can be a factor, the fluid dynamics is complex, as depicted in Fig. 2. Various experimental studies confirm that the structure of the flow past a surface-mounted cube is sensitive

to both the form of the upstream velocity and the plate boundary conditions. The large-scale, low-frequency vortex shedding off the back of the cube necessitates the use of a time-dependent algorithm to correctly predict time-averaged properties [1]. An understanding of this flow pattern is crucial to predicting turbulent airflows along an air vehicle's intended flight path, in addition to maintaining stable flight throughout mission execution [2].

The complex interactions between terrain geometry, varying meteorological conditions, and the overall physical conditions exhibited by man-made structures make urban aerodynamics exceptionally complicated [4–6] and the small size of the UAS that can actually be carried and deployed by individual ground troops makes them especially susceptible (e.g., stability and control) to these dynamics [7]. Complex terrain includes features such as urban canyons, mountains, and heavily wooded areas and can cover large, three-dimensional, geographic areas with widely variable temporal and spatial conditions. Figure 3 illustrates the impact of urban terrain on the boundary layer. On a macro scale, urban terrain tends to slow the airflow down

Figure 2. Idealized flow field over a surface-mounted cube [3].

Figure 3. Schematic of urban boundary layer and effects of varying geometry on airflows [8]. Profiles are percentages of gradient wind.

and increase the height of the boundary layer; however, inside the urban canopy layer, buildings in close proximity to one another shed vortices that support large, dynamic recirculation zones which, in turn, push local winds perpendicular to, in reverse to, or even faster downstream than the prevailing wind. In the urban environment, the characteristic scale is on the order of a few meters.

The Environment Characterization Toolset

Air vehicle system designers traditionally employ a combination of controlled wind

tunnel experiments, field trials, and modeling [9–11] in order to characterize air vehicle flight performance requirements and capabilities. Under the tenets of simulation-based design, such experiments and field trials can provide useful data for model refinement, but lack the test environment control needed for validation. In many cases, such experimentation is prohibitively expensive and, under many scenarios, the return on investment is small. Additionally, when investigating the complex flow fields within environments such as the urban canopy, existing wind tunnels provide limited applicability to urban

airflow applications as they are incapable of matching flow conditions at commonly used model scales.

In order to accurately replicate flow conditions over a scaled model in a wind tunnel, the analyst/engineer must carefully match several key parameters that govern a particular class of flows. These parameters associated with external airflows which drive urban aerodynamics include geometric similarity, intensity of turbulence, turbulence length scale, surface roughness, Reynolds number (ratio of inertial to viscous forces), and Richardson number (ratio of buoyancy to vertical shear effects) [12].

Because experimental facilities are not yet available that replicate the primary physics of the urban problem and because field trials are often prohibitively expensive or logistically impossible, there is a need for accurate, high-fidelity air flow models to help reduce risk of failure and to better understand the physics of UAS surveillance and engagement missions. Owing to the magnitude of the variables involved, the appropriate tool for studying and defining the urban environment is LES [13]. Figure 4 shows the airflow velocity contours from an LES run for Washington D.C. Solutions from these simulations can assist in defining the control authority needed for UAS on board flight control systems to maintain flight stability under varying environmental conditions. Analyzing flow characteristics such as average wind speed changes and correlation to the prevailing meteorological conditions can provide an operating envelope (i.e., area(s) in which UAS

flight is suitable) to design UAS airframes for urban employment, and provide better prediction of near-term local conditions for mission planning and rehearsal.

M&S COMPONENTS

The authors have had considerable experience over the last decade in the development of UAS technologies and the subsequent evaluation and maturation of these technologies through actual flight testing. This real-world experience and the ensuing observations became the impetus for the development of the physics-based modeling and simulation tool described herein. As operational requirements evolved to demand precision operation of UAS within more complex environments, the challenges became readily apparent, but the results were not always intuitive. To illustrate this point, the authors have focused a large portion of their research toward persistent observation and engagement of targets via placement of sensors, and lethal and nonlethal payloads. Flight experiments prior to the development of the M&S tool had shown that large inconsistencies existed in the ability to approach a moving or stationary target with reliable accuracies of less than 1 m. Observations from testing indicated that unsteady winds played a large role. However, it was not intuitively obvious as to the root cause (vehicle aerodynamics, autopilot, flight path, etc.) and the best “system” solution for improving accuracy with the necessary repeatability. The M&S tool

Figure 4. Flow over an urban environment; snapshot of velocity contours 2 m above terrain level predicted by LES [14].

was subsequently developed with a sufficient level of physics, both semi-empirically and analytically derived, to interrogate both individual and coupled mission elements.

As depicted in Fig. 1, the fundamental architecture of the UAS M&S environment comprises three major stand-alone sub-models: the environmental sub-model, the platform sub-model, and the synthetic environment sub-model. Each of these sub-models is described in more detail below.

Environmental Sub-Model

Comprised of everything necessary to model the environment in which the UAS will operate, this sub-model includes components such as the urban terrain, accurate air flow models (as described above), and representations of communication systems. The terrain must not only accurately represent elevation, structures, and other relevant features (e.g., roads and bridges), but it must also contain data about its fundamental properties to support sensor modeling. Available on-board sensors will interact differently with a glass building than a concrete bridge. This “smart” terrain also drives the underpinning of the air flow models, and for especially complex terrains, these models are quite difficult to create and validate. Not only are they greatly affected by the thousands of varying “objects” embedded in the terrain itself, but they necessarily change as a function of time—they are unsteady, requiring the model fidelity the authors have heretofore motivated. Finally, accurate communications modeling is critical to predict overall success of UAS missions in complex environments. Factors such as line of sight, propagation loss, refraction, radio type, and encryption protocols must all be accounted for (see the section titled “UAS Mission Planning Includes Communications Modeling”).

Platform Sub-Model

This sub-model integrates elements of the vehicle flight dynamics with air flow data to capture the complex air flow/vehicle interactions. These interactions are large drivers of overall mission success, are difficult to model, and are treated more thoroughly in

Cybyk *et al.* [7]. The platform sub-model must also capture the specific control algorithms for the modeled platforms, the subsystems that comprise the platforms (e.g., power and navigation), and effectively model payloads (e.g., sensors). Specific challenges in the platform model revolve around how much fidelity in each subcomponent is necessary to sufficiently answer the questions at hand. Also paramount is the feature of modularity previously mentioned. Much of the power of this M&S approach to UAS systems engineering derives from the ability to quickly exchange components (e.g., control algorithm A vs control algorithm B) to perform trade studies and analysis of alternatives in an end-to-end, system-level environment.

Synthetic Environment Sub-Model

This third sub-model integrates all the sub-models discussed above into an end-to-end analysis framework and, as such, must handle synchronization of data, interoperability of M&S components, and overall scenario control. In addition, the synthetic environment provides a visual component to the modeled terrain and platforms as well. This visualization feature not only results in a tool beneficial for training and mission planning, but also creates a useful analysis tool. Because of the complexity of UAS missions in complex environments, the potentially high numbers of entities involved (UAS, ground sensors, warfighters, etc.), and the number of variables that correlate with mission success or failure, the ability to visualize everything that is happening in a given scenario simultaneously provides the human operator the ability to synthesize data and draw conclusions that would likely not be apparent from engineering plots.

Scenario Background

Given the current US operations in the Middle East, a 5 km² area of downtown Baghdad (Fig. 5) was chosen in order to examine the operational relevance of small UAS operations to intelligence gathering in urban scenarios and to provide a use case for baseline evaluation. The flight path flown by the UAS in benign wind conditions is depicted by the

Figure 5. Urban area of 5 km² area of downtown Baghdad modeled for analysis.

dark line. Preliminary analysis using this baseline use case is presented in the following sections.

USE OF UAS M&S ENVIRONMENT

M&S can and should be employed to support the entire systems engineering life-cycle for UAS development and deployment. The development segment involves system design, analysis of alternatives, trade studies, and flight test support, and, indeed, much of our approach here leverages the work done in the systems engineering community in the area of model-based systems engineering (MBSE), as described in Estefan [15] and Weiss and Kathryn [16]. The deployment segment of the life-cycle usually leverages M&S for mission planning, training, and investigation of anomalies. This section provides examples of how the UAS M&S environment can be utilized during both segments.

Actual flight testing is performed using the Procerus Technologies Unicorn air vehicle test platform. The Unicorn is a molded-foam air vehicle that can be built to a 48 or 60 in. wingspan. Equipped with the commercial off-the-shelf Kestrel autopilot, it is

hand-launched. Its electric motor can provide test flights of approximately 1-h duration at speeds of 25–45 mph, depending on environmental conditions. Payloads of up to 1 lb can be accommodated, including a communications package operating within the 900 MHz–2.4 GHz frequency spectrum providing a line-of-sight range of 5 miles. The Procerus Technologies Unicorn air vehicle is modeled in the platform sub-model [17].

Figure 6 illustrates the Unicorn UAS operating in the synthetic Baghdad described above. In addition to the telemetry information for the vehicle, the visualization shows the direction and magnitude of the local wind (dark grey vector pointing toward the vehicle) and the ground speed of the UAS (light grey vector pointing in the direction of travel). The light grey line in the figure illustrates the intended path of the UAS, so at the moment depicted in Fig. 6, the UAS is below and slightly to the left of its desired location due to the effects of the wind.

UAS Sensor Trade Studies

In addition to providing a synthetic environment for the analyst to visualize the operation of the UAS without having to digest and

Figure 6. Procerus Technologies Unicorn UAS in synthetic environment.

Figure 7. Synthetic camera model for Procerus UAS.

fuse the information from multiple plots (e.g., latitude, longitude, altitude, pitch, yaw, and roll vs. time), the platform sub-model also enables high fidelity sensor modeling and evaluation. Figure 7 shows the camera view from the Procerus UAS. The view mimics the actual field of view and look-down angle of the on-board gimballed optical sensor.

The synthetic environment also supports the modeling of other sensor types such

as infrared (IR) (Fig. 8), provided that the appropriate material properties are modeled in the terrain, as described in the section titled “Environmental Sub-Model.”

By including the sensor models in the simulation, the M&S user is able to assess the mission impact of the sensor choice and its associated capabilities. Performing sensor trade studies (to determine which ones are optimal for which missions/platforms)

Figure 8. Synthetic infrared (IR) camera model.

by examining sensor capabilities in isolation would likely result in the selection of a sensor with the greatest capabilities. The UAS environment simulation allows the analyst to assess the performance of different sensors as they are integrated on the UAS platform in a mission-level, end-to-end context. As is sometimes the case, the most capable sensor is not always required or even able to achieve mission success. Utilization of the UAS environment simulation allows the analyst to optimize the system in terms of the mission requirements as against assuming that the optimal system is a sum of the most capable components.

Monte Carlo Analysis for UAS Mission Planning

The number of parameters associated with mission success in such dynamic environments makes it difficult to quantify this success in any kind of closed form. Therefore, optimizations and trades must be derived from intelligent use of statistical design of experiments and Monte Carlo analysis. One of the most important features of the synthetic environment model described above is the ability to remove the visualization component and analyze the rest of the M&S

components in many-iteration scenarios, varying the input parameters to derive performance sensitivities of small UAS to factors in the operational environments in which they will be deployed. This feature provides the capability to still maintain an end-to-end, mission-level perspective, yet at the same time modify input parameters “in-the-loop” and derive overall mission-level measures. It is there that synchronization and scenario control become important, as it is no trivial task to run the potentially dozens of independent models in tandem to achieve a unified mission execution.

This Monte Carlo feature certainly allows for trade studies while systems are being designed and built—with the overall goal of optimizing the airframe and mission systems to function in such complex environments. The *same* toolset, however, can be used for mission planning as well. The envisioned use of the tool in the field involves operators inputting real-time environmental and platform data, and receiving identification of no-fly zones in return. Then the mission planner could create a mission plan and use the Monte Carlo feature to compute a probability of

mission success given the environmental conditions. With the addition of autorouting functionality, the tool would be able to create mission plans that maximize or minimize an objective or a weighted combination of objectives set by the mission planner (e.g., maximize probability of mission success, maximize time on station, minimize time to target, and maximize communications connectivity). In this case, the Monte Carlo feature would be used to more accurately compute the objective measures in this dynamic environment.

Figures 9–11 illustrate example results of 30 simulation runs for a planned mission in which the prevailing wind is 27 knots from the northeast. A prevailing wind speed of

27 knots would be considered higher than normal for the area modeled, but it is not an unreasonably high value. The figures depict the position deviation from the planned route as a function of mission time (X - longitudinal, Y - lateral, and Z - vertical). These figures illustrate the uncertain and unsteady nature of the urban aerodynamic environment. At this wind speed, mission success and failure were completely determined by mission start time in this simulation run (i.e., all other input variables, such as trajectory and wind speed, were held constant).

Figures 9 and 10 illustrate several cases where a strong horizontal wind gust blew the UAS completely off course at around $T + 1000$ s (within 17 min of initialization).

Figure 9. Example Monte Carlo results: Longitudinal path deviation.

Figure 10. Example Monte Carlo results: Lateral path deviation.

Figure 11. Example Monte Carlo results: Vertical path deviation.

Figure 11 displays several mission failures due to a large down draft at approximately $T + 1300$ s (or within 22 min of initialization).

In addition to this relatively simple example of trajectory following, the authors have used these same techniques on a broader scale to answer questions of how effectively various unmanned platforms of different size, service ceiling, endurance, and payload capabilities can respond to missions such as nuclear forensics and biochemical disaster response. While the details of these studies are beyond the scope of this article and are currently ongoing, they demonstrate the capabilities of the UAS M&S tool to address UAS performance in a mission-level operational context.

UAS Mission Planning Includes Communications Modeling

As mentioned earlier, communications between multiple UAS and/or from the UAS to a ground station is an important factor in the success of UAS operation. Without communications, the UAS is unable to send real-time sensor data to the operator. In addition, should communications be lost, current UAS systems typically terminate their mission flight path and either return to base or fly to a loiter point with the hopes of restoring communications. The ability to maintain communications throughout the mission is typically not part of the mission planning process. This problem is exacerbated by urban and mountainous

terrain and areas where communications jamming is present. As a result, there is a need to model, with high fidelity, the UAS communications environment. Such a model already exists in the Tactical Edge Network Emulation Tool (TENET) [18], which was specifically designed to handle the challenges of ad hoc, dynamic networking analysis and modeling, such as line-of-sight, propagation loss, refraction, radio type, and encryption protocols, and, as mentioned above, has been fully incorporated into the UAV M&S environment described in this article.

Figure 12 depicts a UAS and its available communication paths (light grey lines extending to the right) to the other nodes in its network at a given time in the modeled scenario. In addition to the aforementioned analysis of UAS operations in complex aerodynamic environments, the M&S operator/analyst has the capability to analyze the ability of the different communication systems and architectures to function in a complex communications environment, while the mission planner is able to plan the UAS path and associated ground station placement in order to ensure mission success from a communications standpoint.

Understanding the Effects of the Environment on Power Systems

In order to be effective, small UAS platforms will also be required to transit from their launch points to their intended patrol areas, perform their mission over a given

Figure 12. Lines of communication from a UAS in the UAS M&S environment.

time period, and return to friendly territory for recovery. Just as pilots of manned aircraft plan their fuel loads to accomplish similar missions (albeit on a larger scale), the UAS operator and mission planner must work together to ensure that their assets are able to meet mission goals. A part of that mission planning process is a detailed understanding of power consumption and its effect on mission completion rates. Such a tool as developed by the authors would enable mission planners to investigate alternative routes of flight to the intended operating area and return. Figure 13 shows the effects of wind on power consumption for a mission of 1-h duration.

As the air vehicle fights to overcome the effects of the wind, the engine accelerates and decelerates to maintain the required speed to transit along the intended flight path and meet its time gates (grey line with large fluctuations). The other line that drops from 11.5 VDC to 9.3 VDC depicts the effects of this “throttling” on power consumption, and therefore battery drain, with all mission systems operating. In this particular case, the air vehicle was able to meet its mission goals as planned. In other cases, should mission goals exceed the capabilities of the air vehicle systems, alternative

routes of flight can be planned and examined. Ultimately, the authors intend to incorporate an autorouting capability that will enable the simulation to determine a flight path that maximizes the probability of mission success under varying environmental conditions.

M&S VALIDATION VIA FLIGHT TESTING

M&S and flight testing have many interdependencies when it comes to assessing the capabilities and performance of UAS. M&S supplements, but does not replace, flight testing in that the operator can inexpensively run many different variations and test the system in environmental conditions or locations that are not possible to replicate in flight testing (e.g., urban). However, the M&S must be validated for its results to be useful and believable. Validation is typically achieved by comparing simulation data to flight test data. The authors have conducted several flight tests with the Procerus Unicorn UAS that is modeled in the simulation. Flight testing has resulted in the adjustment of the aerodynamic data in the simulation, validation of the autopilot model, and creation of an empirical battery model. Flight testing has also illustrated the difficulty in operating small

Figure 13. Effects of wind on power consumption.

UAS in unsteady aerodynamic environments. In the field tests, the unsteady aerodynamic environment was caused by gusty winds on the flight test range, but it raises the concern about operation in urban environments where there is a desire to operate but, currently, have no test facilities. For the foreseeable future, testing of UAS operation in urban environments will have to be performed in M&S similar to the UAS simulation described herein.

SUMMARY AND CIVILIAN APPLICATIONS

The maturing of UAS operations for large battlefield engagements has been ongoing for well over a decade. The utility to the warfighter of high- and medium-altitude UAS has been proven in the heat of battle, and large amounts of funding have been focused on developing and tailoring these systems to more efficiently target, track, and engage the enemy. For these systems that operate well above the battlespace and problematic terrain features, modeling of the environment/vehicle interactions is not necessary. However, for smaller, man-portable

UAS that are common at the company level and below, the need to operate within these complex environments is a fundamental element of today's warfare. Consequently, the ability to have an M&S tool that enables operators to train and conduct mission planning including determining flight paths, identifying no-fly zones, and selecting mission-specific UAS configurations is critical.

Until recently, no such tool existed and the warfighter intuitively operated significantly above terrain features that would compromise the ability of the UAS to successfully complete its mission. As the use of the small UAS within complex terrain environments becomes more commonplace, information such as assessment of enemy positions, strengths, and anticipated countermeasures can be provided at the company level in real time. As the fidelity of the M&S increases, a strong emphasis can then be placed on maturing small, low-altitude air vehicles and increasing their reliability and productivity.

Envisioned capability requirements for these small units will include persistent intelligence, surveillance, and reconnaissance (ISR) for force protection, over-the-horizon ISR, and rapid engagement of threats.

To address these requirements, advanced technologies will have to be incorporated onto smaller air vehicle platforms. These technologies include networking between vehicles for decentralized, autonomous operation of multiple UAS by one operator, non-line-of-sight (NLOS) communications, and the incorporation of targeting devices and small, lethal and nonlethal payloads. The M&S framework described in this article provides the ability to evaluate the complex interactions between numerous technological and environmental factors leading to a solution for the warfighter with measurable technological advantages.

The use of high-altitude UAS such as Predator and Global Hawk has in recent years been expanded to include numerous civilian applications. These applications use common sets of military-developed sensor payloads and have been readily adapted to safely provide persistent ISR within the continental US. Missions where these systems have been employed include fire fighting in California, humanitarian assistance after hurricane Katrina, port security, and border patrol. Similar to their military counterparts, these systems are designed for coverage of large areas and do not require the high-fidelity M&S (that capture environment/vehicle interactions) in order to achieve mission success.

The use of these small air vehicles for civilian applications in densely populated urban regions has brought to the forefront the challenge of air-space de-confliction between UAS and manned aircraft. A means to assess the issues with this challenge is an M&S tool, similar in architecture to its military counterpart that appropriately captures not only the environment/vehicle interactions, but also the integration of the UAS into an active and ever-changing airspace. When this challenge is overcome, one can envision many uses for such smaller assets such as close-in inspection from many viewing angles including persistent ISR for crowd observation (e.g., for large sporting events and protests), infrastructure surveillance (e.g., power plants, bridges, and water supplies), port security, and other law enforcement applications.

USE OF LAGRANGE INTERPOLATING POLYNOMIALS IN THE RLT

WARREN P. ADAMS
Clemson University, Clemson,
South Carolina

An effective strategy for solving a mixed 0–1 optimization program is to form tight polyhedral outer approximations of the convex hull of feasible solutions, and to then use linear programming relaxations to obtain bounds. A substantial body of work has shown how such approximations can be automatically generated in higher-dimensional spaces through a two-step *reformulation-linearization technique* (RLT). In a basic RLT implementation, polynomial representations of a mixed 0–1 program are computed in the reformulation step by multiplying the problem constraints by various “functional factors” consisting of the binary variables x and their complements $1 - x$, and by using the idempotent property that $x^2 = x$. The higher-dimensional spaces are obtained in the linearization step by substituting a continuous variable for each distinct, nonlinear product term.

It turns out that these functional factors of x and $1 - x$ for mixed 0–1 programs are part of a much larger family of functions, called *Lagrange interpolating polynomials* (LIPs), that can be used to generalize this idempotent property so as to encompass discrete variables. As a consequence, the LIPs allow the RLT to extend to mixed-discrete programs. This article reviews the role of LIPs in the RLT process to construct tight approximations and convex hull representations for mixed-discrete programs. The LIP approach was first introduced in Adams and Sherali [1,2, Chapter 4] where comprehensive descriptions are available.

The RLT for mixed 0–1 sets is briefly summarized in the next section. This summary reviews the steps of *reformulation* and *linearization*, and serves as a foundation and basis of comparison for the use of LIPs in the more general discrete framework.

RLT FOR MIXED-BINARY SETS

Consider the mixed 0–1 set

$$\begin{aligned} \mathbf{X} &\equiv \{(\mathbf{x}, \mathbf{y}) \in \mathbb{R}^n \times \mathbb{R}^p : \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{y} \geq \mathbf{b}, \\ 0 &\leq x_j \leq 1 \quad \forall j \in N, \\ x_j &\in S_j \quad \forall j \in N, \mathbf{L} \leq \mathbf{y} \leq \mathbf{U}\}, \end{aligned} \quad (1)$$

where $N \equiv \{1, \dots, n\}$, and where each variable x_j can realize values in the associated discrete set $S_j \equiv \{0, 1\}$, for all $j \in N$. The matrices $\mathbf{A}$ and $\mathbf{B}$ are $m \times n$ and $m \times p$, respectively, $\mathbf{x} \in \mathbb{R}^n$, $\mathbf{y} \in \mathbb{R}^p$, and $\mathbf{b} \in \mathbb{R}^m$. The $\mathbf{y}$ variables are continuous with finite lower and upper bounds $\mathbf{L}$ and $\mathbf{U}$, respectively. As noted in various contexts within Adams and Sherali [1–4], these bounds can be assumed, without loss of generality, to be scaled to lie within the unit interval.

The RLT [2–4] for sets of the form $\mathbf{X}$ constructs an $(n + 1)$ -level hierarchy of linearizations that ranges from the usual continuous relaxation at level-0 to the convex hull of feasible solutions at level- n . It operates as follows. Level-0 is that relaxation obtained by omitting the restrictions $x_j \in S_j$ for all $j \in N$. For each $d \in N$, the level- d representation is computed using the two steps of *reformulation* and *linearization* as follows.

Computation of the level- d RLT of Equation (1)

Step 1. Reformulation: For each $J \subseteq N$ with $|J| = d$, compute the product of each of the 2^d nonnegative “functional factors” $\prod_{j \in J_1} x_j \prod_{j \in J \setminus J_1} (1 - x_j)$ for all sets $J_1 \subseteq J$ with every inequality defining $\mathbf{X}$ of Equation (1), except for those bounding restrictions $0 \leq x_k \leq 1$ having $k \in J$. (For $d = n$, include $\prod_{j \in J_1} x_j \prod_{j \in N \setminus J_1} (1 - x_j) \geq 0$ for all sets $J_1 \subseteq N$ to replace the multiplication of the functional factors with the bounding restrictions $0 \leq x_k \leq 1$ since $J = N$.) Replace all the constraints found within Equation (1) with these newly defined restrictions. Use the

idempotent property of binary variables to set $x_j^2 = x_j$ for all $j \in N$.

Step 2. Linearization: For each $J \subseteq N$ with $2 \leq |J| \leq \min\{d+1, n\}$, substitute a continuous variable w_J for each resulting nonlinear term $\prod_{j \in J} x_j$. For each $J \subseteq N$ with $1 \leq |J| \leq d$, substitute a continuous variable v_{Jk} for each nonlinear term $y_k \prod_{j \in J} x_j$. Call the resulting polyhedral set in the variables $(\mathbf{x}, \mathbf{y}, \mathbf{w}, \mathbf{v})$ as $\mathbf{X}_d$.

For clarification, given any $J \subseteq N$, the reformulation step does not multiply functional factors of the form $\prod_{j \in J_1} x_j \prod_{j \in J \setminus J_1} (1 - x_j)$ for $J_1 \subseteq J$ by any restrictions $0 \leq x_k \leq 1$ having $k \in J$ since the resulting inequalities would be implied by $\mathbf{X}_d$. Given any such $J_1 \subseteq J$, multiplication of this expression by some $x_k \geq 0$ having $k \in J \setminus J_1$ or by some $1 - x_k \geq 0$ having $k \in J_1$ trivially simplifies to $0 \geq 0$, while multiplication by some $x_k \geq 0$ having $k \in J_1$ or by some $1 - x_k \geq 0$ having $k \in J \setminus J_1$ makes this same expression nonnegative. In the latter case, for $d \leq n-1$, the inequality $\prod_{j \in J_1} x_j \prod_{j \in J \setminus J_1} (1 - x_j) \geq 0$ is implied by (summing) the two inequalities $\prod_{j \in J_1 \cup \{k\}} x_j \prod_{j \in J \setminus J_1} (1 - x_j) \geq 0$ and $\prod_{j \in J_1} x_j \prod_{j \in (J \cup \{k\}) \setminus J_1} (1 - x_j) \geq 0$ computed in level- d , where k is any index having $k \in N \setminus J$. For $d = n$, all 2^n possible such inequalities with $J = N$ are enforced. Notably, these 2^n inequalities are implied in the set $\mathbf{X}_n$ if there exist any continuous variables $\mathbf{y}$ in $\mathbf{X}$, due to their multiplication with the inequalities $\mathbf{L} \leq \mathbf{y} \leq \mathbf{U}$.

Now, for $d \in N$, the set $\mathbf{X}_d$ possesses two important properties. The first is that, for each such d , the variables $\mathbf{w}$ and $\mathbf{v}$ will equal their intended products for binary $\mathbf{x}$. This has the RLT providing a hierarchy of equivalent mixed 0–1 linear reformulations of $\mathbf{X}$, when $x_j \in S_j$ for all $j \in N$ is enforced within the sets $\mathbf{X}_d$.

The second property involves projections of the sets $\mathbf{X}_d$. Denote the projection of each set $\mathbf{X}_d$, for $d \in \{0, 1, \dots, n\}$, onto the space of the variables $(\mathbf{x}, \mathbf{y})$ as $P_{(\mathbf{x}, \mathbf{y})}(\mathbf{X}_d)$, where

$$P_{(\mathbf{x}, \mathbf{y})}(\mathbf{X}_d) \equiv \{(\mathbf{x}, \mathbf{y}) : (\mathbf{x}, \mathbf{y}, \mathbf{w}, \mathbf{v}) \in \mathbf{X}_d \text{ for some } (\mathbf{w}, \mathbf{v})\}. \quad (2)$$

Then the second property is as follows:

$$\begin{aligned} \mathbf{X}_0 &= P_{(\mathbf{x}, \mathbf{y})}(\mathbf{X}_0) \subseteq P_{(\mathbf{x}, \mathbf{y})}(\mathbf{X}_1) \\ &\subseteq \dots \subseteq P_{(\mathbf{x}, \mathbf{y})}(\mathbf{X}_n) = \text{conv}(\mathbf{X}). \end{aligned} \quad (3)$$

The first equation is due to $\mathbf{X}_0$ containing no $(\mathbf{w}, \mathbf{v})$. The family of containments follows from each inequality defining $\mathbf{X}_{d-1}$ being implied by two inequalities defining $\mathbf{X}_d$, for all $d \in N$. The convex hull is established by showing that each extreme point to the polytope $\mathbf{X}_n$ has $\mathbf{x}$ binary, which, together with the first property, ensures that all linearized variables equal their intended products at the extreme points of this highest-dimensional space.

The above construction of the sets $\mathbf{X}_d$ is the foundational RLT implementation. Extensions and generalizations exist. Special structures such as SOS type constraints [5] lead to different functional factors that promote more concise and tighter representations. Conditional logic arguments that exploit the nonlinear nature of the generated inequalities in the reformulation step also lead to tighter forms [5,6]. Equality restrictions promote more concise representations without forfeiting strength [4, pp. 104–105].

Various optimization problems are accommodated by the generated polytopes $\mathbf{X}_d$ and the linearization process. Polynomial objective functions that are linear in $\mathbf{y}$ for fixed $\mathbf{x}$ can be optimized over the sets $\mathbf{X}_d$, provided the selected level- d is large enough to handle the nonlinear terms. Polynomial terms in the constraints are also suitably treated. Extensions handle semi-infinite programs and general convex functions [7]. Moreover, tight relaxations are obtained for general polynomial programs containing products amongst the variables $\mathbf{y}$ themselves [8], such as bilinear programs [9], although the convex hull arguments are not applicable in such cases.

The sets $\mathbf{X}_d$ promote partial convex hull representations. Given any nonempty set $J \subseteq N$, the variables x_j for $j \in N \setminus J$ can be treated as continuous and grouped within $\mathbf{y}$. It then follows that the level- $|J|$ RLT representation over the full complement of remaining binary variables in this modified set, when projected onto the original $(\mathbf{x}, \mathbf{y})$ variable space, provides $\text{conv}(\mathbf{X} \cap x_j \text{ binary } \forall j \in J)$. In fact, a

special case of this argument having $|J| = 1$ is used in Balas *et al.* [10] for generating the convex hull with respect to a single variable x_j , so that $J = \{j\}$.

The increasing strengths of the hierarchical levels, coupled with the explicit convex hull representation at $\mathbf{X}_n$, also provide conditions under which optimal solutions to the continuous relaxations of mixed-binary programs afford direct information relative to the discrete optimum. Inductive arguments [11,12] that systematically progress up the hierarchical levels from $\mathbf{X}_0$ to $\mathbf{X}_n$ identify structures for which binary variables realizing values of 0 or 1 in a continuous optimum will *persist* in retaining these values at the discrete optimum.

Early theoretical and computational contributions to the RLT dealing with quadratic objective functions are recorded in the work of Adams and Sherali [13–15], and computational successes on the famous quadratic assignment problem, both in terms of bound strength and enumerative results, are collectively found in the work of Johnson [16], Adams and Johnson [17], Hahn *et al.* [18], and Adams *et al.* [19]. Other computational results are summarized in the work of Sherali and Adams [2,20].

LAGRANGE INTERPOLATING POLYNOMIALS AND KRONECKER PRODUCTS

Two critical ingredients of the RLT for mixed-binary programs are (i) the multiplication of functional factors with the constraints defining $\mathbf{X}$ and (ii) the enforcement that $x_j^2 = x_j$ for binary x_j . Indeed, this latter ingredient is the step that affords strength to the RLT representations. It turns out that both are extendable to more general regions where the variables x_j are discrete, and allowed to take values within finite sets. To make this extension, the functional factors are replaced with LIPs, and the multiplication of such LIPs with constraints of $\mathbf{X}$ is expressed as Kronecker products of matrices. These two concepts are explored below in preparation for the RLT extension to mixed-discrete programs of the section titled “RLT for Mixed-Discrete Sets.”

Lagrange Interpolating Polynomials

Reconsider the variables x_j , for $j \in N$, of the preceding section, but this time allow each x_j to realize values in some finite set $S_j \equiv \{\theta_{j1}, \dots, \theta_{jk_j}\}$ for a given nonnegative integer k_j . In this manner, each S_j found in Equation (1) is a special case having $k_j = 2$ with $\theta_{j1} = 0$ and $\theta_{j2} = 1$. Associated with each x_j are k_j LIPs (for example, see Horn and Johnson [21, pp. 29–30]). Letting $K_j \equiv \{1, \dots, k_j\}$ for each $j \in N$, these LIPs are computed in terms of the elements in S_j as follows:

$$L_{jk}(x_j) = \frac{\prod_{i \in K_j \setminus \{k\}} (x_j - \theta_{ji})}{\prod_{i \in K_j \setminus \{k\}} (\theta_{jk} - \theta_{ji})} \quad \forall(j, k), k \in K_j, j \in N. \quad (4)$$

For each $j \in N$, the k_j functions $L_{jk}(x_j)$ are polynomials of degree $k_j - 1$ for all $k \in K_j$. They possess the three important properties given below. Here, Properties 2 and 3 are derived from Property 1 but are emphasized because of their significance in an RLT implementation.

Properties of the LIPs of Equation (4), for $j \in N$

1. For each $x_j \in S_j$, $L_{jk}(x_j) = 1$ if $x_j = \theta_{jk}$ and $L_{jk}(x_j) = 0$ otherwise, for all $k \in K_j$.
2. For each $x_j \in S_j$, $L_{jk}(x_j)x_j = L_{jk}(x_j)\theta_{jk}$ for all $k \in K_j$.
3. For each $x_j \in S_j$, $L_{jk}(x_j)L_{ji}(x_j) = L_{jk}(x_j)$ if $i = k$ and $L_{jk}(x_j)L_{ji}(x_j) = 0$ otherwise, for all (i, k) with $i \in K_j$ and $k \in K_j$.

Four immediate consequences of these properties are as follows. First, for each $j \in N$, Property 1 has $L_{jk}(x_j) \geq 0$ for all $k \in K_j$ regardless of the original defining set S_j . Second, for the special case in which $k_j = 2$ with $S_j = \{0, 1\}$ so that x_j is a binary variable, the functions $L_{j1}(x_j)$ and $L_{j2}(x_j)$ reduce to the nonnegative RLT functional factors $1 - x_j$ and x_j respectively, for mixed 0–1 linear programs. Third, Properties 2 and 3, which simplify the multiplication of $L_{jk}(x_j)$ for $k \in K_j$ with the variable x_j and with the functions $L_{ji}(x_j)$ for $i \in K_j$ respectively,

can be considered as generalizations of the idempotent property for binary variables x_j . Specifically, for the special case where $k_j = 2$ and $S_j = \{0, 1\}$, Properties 2 and 3 each enforce that $x_j^2 = x_j$.

The fourth consequence follows from Property 1, and is motivated by the linearization step of the RLT for mixed 0–1 programs described in the previous section. Given a discrete variable x_j that can realize k_j values, compute the associated k_j LIPs of degree $k_j - 1$. Letting $\mathbf{x}^j$ denote the column vector in $\mathbb{R}^{k_j}$ whose i th entry is x_j^{i-1} , the (redundant) k_j inequalities restricting these LIPs to nonnegative values are represented in matrix form as $C_j \mathbf{x}^j \geq \mathbf{0}$, where C_j is that $k_j \times k_j$ matrix having entry (k, i) given by the coefficient on x_j^{i-1} in $L_{jk}(x_j)$. Here, and throughout, the notation $\mathbf{0}$ is used to represent a suitably dimensioned vector having all entries of 0. Property 1 provides that the matrix C_j is invertible with $C_j^{-1} = V_j^T$, where V_j is the $k_j \times k_j$ Vandermonde matrix whose (k, q) th entry is θ_{jk}^{q-1} for each $k \in K_j$, where $0^0 = 1$ for convenience. Now compute the polyhedral region $C_j \{\mathbf{x}^j\}_L \geq \mathbf{0}$ in $\mathbb{R}^{k_j}$ by linearizing $\mathbf{x}^j$ to $\{\mathbf{x}^j\}_L$, obtained by replacing each nonlinear term with a continuous variable. (In the remainder of this article, the notation $\{\bullet\}_L$ is used to denote the linearized form of $\bullet$ that is obtained by substituting a continuous variable for each distinct nonlinear term.) Then, since the first entry of $\{\mathbf{x}^j\}_L$ is 1 and the first row of V_j^T consists entirely of entries of value 1, it follows that $C_j \{\mathbf{x}^j\}_L \geq \mathbf{0}$ is a polytope in $\mathbb{R}^{k_j}$ whose extreme points are the columns of the matrix V_j^T less the first row.

This fourth consequence is stated formally as follows.

Lemma 1. *Given any variable x_j that can realize k_j values in some discrete set $S_j = \{\theta_{j1}, \theta_{j2}, \dots, \theta_{jk_j}\}$, the polyhedral set*

$$P_j = \{\{\mathbf{x}^j\}_L : C_j \{\mathbf{x}^j\}_L \geq \mathbf{0}\},$$

where $C_j \{\mathbf{x}^j\}_L \geq \mathbf{0}$ denotes that linear system in k_j inequalities and $k_j - 1$ variables obtained by linearizing the associated system $C_j \mathbf{x}^j \geq \mathbf{0}$ has the following property. There is a one-to-one correspondence between the

extreme points of P_j and the k_j possible realizations of x_j having $x_j \in S_j$, with $\{\mathbf{x}^j\}_L = \mathbf{x}^j$ at each such point.

Example 1. Consider the discrete variable $x_1 \in S_1 = \{-1, 0, 2\}$. Then the $k_1 = 3$ linear inequalities $C_1 \{\mathbf{x}^1\}_L \geq \mathbf{0}$ define the polytope P_1 given by

$$P_1 = \left\{ \begin{pmatrix} 1 \\ x_1 \\ \ell_1 \end{pmatrix} : \begin{bmatrix} 0 & -\frac{2}{3} & \frac{1}{3} \\ 1 & \frac{1}{2} & -\frac{1}{2} \\ 0 & \frac{1}{6} & \frac{1}{6} \end{bmatrix} \times \begin{pmatrix} 1 \\ x_1 \\ \ell_1 \end{pmatrix} \geq \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix} \right\},$$

where ℓ_1 is used to denote the linearized version of the quadratic term x_1^2 . The inequalities defining P_1 are the nonnegative linearized LIPs, and the extreme points of P_1 are the columns of the matrix $V_1^T = \begin{bmatrix} 1 & 1 & 1 \\ -1 & 0 & 2 \\ 1 & 0 & 4 \end{bmatrix}$ less the first row, as depicted in Fig. 1.

Kronecker Products of Matrices

As a means of applying the RLT to general discrete variables, the LIPs are now the functional factors, multiplied amongst themselves, and with other families of inequalities. These factors replace, and generalize, the expressions $\prod_{j \in J_1} x_j \prod_{j \in J \setminus J_1} (1 - x_j)$ for sets $J_1 \subseteq J \subseteq N$ used in the reformulation step of the section titled “RLT for Mixed-Binary Sets.” This multiplication of LIPs with families of inequalities is most conveniently expressed in terms of Kronecker products of matrices. A brief review of Kronecker products follows.

The Kronecker product of an $m_1 \times n_1$ matrix A_1 with an $m_2 \times n_2$ matrix A_2 , denoted by $A_1 \otimes A_2$, is the $m_1 m_2 \times n_1 n_2$ matrix

$$A_1 \otimes A_2 = \begin{bmatrix} a_{11}A_2 & \dots & a_{1n_1}A_2 \\ \vdots & \ddots & \vdots \\ a_{m_1 1}A_2 & \dots & a_{m_1 n_1}A_2 \end{bmatrix},$$

where a_{ij} represents the (i, j) th entry of A_1 . This definition gives rise to the following two properties of Kronecker products. Here, the scalar r is any integer greater than or equal to 2, and all matrices A_1 through

Figure 1. The polytope P_1 for x_1 realizing values in $S_1 = \{-1, 0, 2\}$.

A_{2r} are assumed compatible for the given multiplications.

Properties of Kronecker products of matrices

1. $A_1 A_2 \otimes A_3 A_4 \otimes \cdots \otimes A_{2r-1} A_{2r} = (A_1 \otimes A_3 \otimes \cdots \otimes A_{2r-1})(A_2 \otimes A_4 \otimes \cdots \otimes A_{2r})$.
2. Given that A_1 through A_r are invertible, $(A_1 \otimes A_2 \otimes \cdots \otimes A_r)^{-1} = A_1^{-1} \otimes A_2^{-1} \otimes \cdots \otimes A_r^{-1}$.

These two properties promote a generalization of Lemma 1 to any finite collection of discrete variables x_j for $j \in J \subseteq N$, as well as insight into earlier convex hull arguments for the RLT. Specifically, consider any set $J \subseteq N$ of discrete variables x_j for $j \in J$, where each variable x_j can realize k_j values. Then the $\prod_{j \in J} k_j$ inequalities obtained by computing all possible products of $|J|$ LIPs, with one LIP taken from each variable x_j , and by setting the resulting products nonnegative, can be expressed as $\otimes_{j \in J} C_j \mathbf{x}^j \geq \mathbf{0}$. Property 1 gives that these same inequalities can be expressed as $(\otimes_{j \in J} C_j)(\otimes_{j \in J} \mathbf{x}^j) \geq \mathbf{0}$, with the linearized version obtained by substituting a continuous variable for each nonlinear term given by $\otimes_{j \in J} C_j \{\otimes_{j \in J} \mathbf{x}^j\}_L \geq \mathbf{0}$. Now, since each C_j has an inverse V_j^T that is the transpose of some Vandermonde matrix V_j as explained in the previous section, Property 2 gives that $(\otimes_{j \in J} C_j)^{-1} = \otimes_{j \in J} V_j^T$. A consequence is that the polytope $\otimes_{j \in J} C_j \{\otimes_{j \in J} \mathbf{x}^j\}_L \geq \mathbf{0}$ in $\mathbb{R}^{\prod_{j \in J} k_j - 1}$ has its extreme points enumerated by the columns of the matrix $\otimes_{j \in J} V_j^T$, less the first row. A formal statement is below.

Lemma 2. *Given any $J \subseteq N$ and any collection of variables x_j , for $j \in J$, such that each x_j can realize k_j values in the discrete set $S_j = \{\theta_{j1}, \theta_{j2}, \dots, \theta_{jk_j}\}$, the polyhedral set*

$$P_J = \left\{ \{\otimes_{j \in J} \mathbf{x}^j\}_L : \otimes_{j \in J} C_j \{\otimes_{j \in J} \mathbf{x}^j\}_L \geq \mathbf{0} \right\},$$

where $\otimes_{j \in J} C_j \{\otimes_{j \in J} \mathbf{x}^j\}_L \geq \mathbf{0}$ denotes that linear system of $\prod_{j \in J} k_j$ inequalities and $\prod_{j \in J} k_j - 1$ variables obtained by linearizing the associated system $(\otimes_{j \in J} C_j)(\otimes_{j \in J} \mathbf{x}^j) \geq \mathbf{0}$, has the following property. There is a one-to-one correspondence between the extreme points of P_J and the $\prod_{j \in J} k_j$ possible realizations of $\otimes_{j \in J} \mathbf{x}^j$ having $x_j \in S_j$ for all $j \in J$, with $\{\otimes_{j \in J} \mathbf{x}^j\}_L = \otimes_{j \in J} \mathbf{x}^j$ at each such point.

Lemma 2 is illustrated in the example below.

Example 2. Consider the two discrete variables x_1 and x_2 having $S_1 = \{-1, 0, 2\}$ and $S_2 = \{0, 1\}$ with $k_1 = 3$ and $k_2 = 2$. Defining the matrices C_1 and C_2 and associated vectors $\mathbf{x}^1$ and $\mathbf{x}^2$ as in the section titled “Lagrange Interpolating Polynomials,” the products of the inequalities representing the three nonnegative LIPs for x_1 with the two nonnegative LIPs for x_2 , given by $C_1 \mathbf{x}^1 \otimes C_2 \mathbf{x}^2$, can be set to nonnegative values to obtain

$$\begin{bmatrix} 0 & -\frac{2}{3} & \frac{1}{3} \\ 1 & \frac{1}{2} & -\frac{1}{2} \\ 0 & \frac{1}{6} & \frac{1}{6} \end{bmatrix} \begin{pmatrix} 1 \\ x_1 \\ x_1^2 \end{pmatrix} \otimes \begin{pmatrix} 0 \\ 1 \end{pmatrix} \geq \mathbf{0}$$

$$\otimes \begin{bmatrix} 1 & -1 \\ 0 & 1 \end{bmatrix} \begin{pmatrix} 1 \\ x_2 \end{pmatrix} \geq \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix} \otimes \begin{pmatrix} 0 \\ 0 \end{pmatrix}.$$

Property 1 with $r = 2$ allows for the rewriting of $C_1 \mathbf{x}^1 \otimes C_2 \mathbf{x}^2$ to $(C_1 \otimes C_2)(\mathbf{x}^1 \otimes \mathbf{x}^2)$. Linearizing the vector $(\mathbf{x}^1 \otimes \mathbf{x}^2)$ to $\{\mathbf{x}^1 \otimes \mathbf{x}^2\}_L$ by substituting a continuous variable for each nonlinear term, this system yields the following polyhedral set, called P_{12} to reflect the variables x_1 and x_2 .

$$P_{12} = \left\{ \begin{pmatrix} 1 \\ x_2 \\ x_1 \\ x_1 x_2 \\ x_1^2 \\ x_1^2 x_2 \end{pmatrix}_L : \begin{bmatrix} 0 & 0 & -\frac{2}{3} & \frac{2}{3} & \frac{1}{3} & -\frac{1}{3} \\ 0 & 0 & 0 & -\frac{2}{3} & 0 & \frac{1}{3} \\ 1 & -1 & \frac{1}{2} & -\frac{1}{2} & -\frac{1}{2} & \frac{1}{2} \\ 0 & 1 & 0 & \frac{1}{2} & 0 & -\frac{1}{2} \\ 0 & 0 & \frac{1}{6} & -\frac{1}{6} & \frac{1}{6} & -\frac{1}{6} \\ 0 & 0 & 0 & \frac{1}{6} & 0 & \frac{1}{6} \end{bmatrix} \times \left\{ \begin{pmatrix} 1 \\ x_2 \\ x_1 \\ x_1 x_2 \\ x_1^2 \\ x_1^2 x_2 \end{pmatrix}_L \geq \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{pmatrix} \right\} \right\}$$

The extreme points of P_{12} are the columns of the matrix $V_1^T \otimes V_2^T$ below, less the first row.

$$V_1^T \otimes V_2^T = \begin{bmatrix} 1 & 1 & 1 \\ -1 & 0 & 2 \\ 1 & 0 & 4 \end{bmatrix} \otimes \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix} \\ = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 \\ 0 & 1 & 0 & 1 & 0 & 1 \\ -1 & -1 & 0 & 0 & 2 & 2 \\ 0 & -1 & 0 & 0 & 0 & 2 \\ 1 & 1 & 0 & 0 & 4 & 4 \\ 0 & 1 & 0 & 0 & 0 & 4 \end{bmatrix}.$$

Lemma 2 provides insight into a convex hull result established in an early work on the RLT. Given a collection of n binary variables indexed as in Equation (1) by the set N , the

paper by Sherali and Adams [3] constructs a special polyhedral set in the following manner. The 2^n inequalities $\prod_{j \in J} x_j \prod_{j \in N \setminus J} (1 - x_j) \geq 0$ for all $J \subseteq N$ are first computed, and then linearized as in the RLT of the section titled “RLT for Mixed-Binary Sets” by substituting a continuous variable w_J for each nonlinear term $\prod_{j \in J} x_j$, to obtain the set

$$\beta = \left\{ (\mathbf{x}, \mathbf{w}) \in \mathbb{R}^n \times \mathbb{R}^{2^n - n - 1} : \left\{ \prod_{j \in J} x_j \prod_{j \in N \setminus J} (1 - x_j) \right\}_L \geq 0 \forall J \subseteq N \right\}.$$

It directly follows from Sherali and Adams [[3] Theorem 2, p. 417] that β is a polytope with 2^n extreme points, and that each extreme point has x_j binary for all $j \in N$, with $w_J = \prod_{j \in J} x_j$ for all $J \subseteq N$ having $|J| \geq 2$. This same result is alternately established by Lemma 2.

RLT FOR MIXED-DISCRETE SETS

Reconsider $\mathbf{X}$ of Equation (1) where the sets S_j for $j \in N$ are as defined in the section titled “Lagrange Interpolating Polynomials” to be $S_j = \{\theta_{j1}, \dots, \theta_{jk_j}\}$ for given nonnegative integers k_j . Assume without loss of generality that $\theta_{j1} < \theta_{j2} < \dots < \theta_{jk_j}$ for each j . Include within $\mathbf{X}$ the nonnegative restrictions on all LIPs, given by $L_{jk}(x_j) \geq 0$ for all (j, k) , $k \in K_j$, $j \in N$, expressed in matrix form as $C_j \mathbf{x}^j \geq \mathbf{0}$ for all $j \in N$. For convenience, the set is stated below.

$$\mathbf{X} \equiv \{(\mathbf{x}, \mathbf{y}) \in \mathbb{R}^n \times \mathbb{R}^p : \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{y} \geq \mathbf{b}, C_j \mathbf{x}^j \geq \mathbf{0} \forall j \in N, x_j \in S_j \forall j \in N, \mathbf{L} \leq \mathbf{y} \leq \mathbf{U}\} \quad (5)$$

Similar to the RLT for mixed-binary sets, the RLT for mixed-discrete sets constructs an $(n + 1)$ -level hierarchy of linearizations, denoted $\mathbf{X}_d$, $d = 0, \dots, n$. The level-0 relaxation is the polyhedral set of Equation (5) without the $x_j \in S_j$ restrictions, and with $\mathbf{x}^j$ replaced by $\{\mathbf{x}^j\}_L$, where the linearized variables are represented by $\mathbf{w}$. All other levels are computed as follows.

Computation of the Level- d RLT of Equation (5)

Step 1. Reformulation: For each $J \subseteq N$ having $|J| = d$, compute the Kronecker products of the $\prod_{j \in J} k_j$ nonnegative functional factors found within $\otimes_{j \in J} C_j \mathbf{x}^j$ with every inequality defining $\mathbf{X}$ of Equation (5), except for those $C_k \mathbf{x}^k \geq \mathbf{0}$ having $k \in J$. (For $d = n$, include $\otimes_{j \in N} C_j \mathbf{x}^j \geq \mathbf{0}$ to replace the multiplication of $\otimes_{j \in J} C_j \mathbf{x}^j$ with the expressions $C_j \mathbf{x}^j \geq \mathbf{0}$ since $J = N$.) Replace all the constraints found within Equation (5) with these newly defined restrictions. Use LIP Property 2 to set $L_{jk}(x_j)x_j = L_{jk}(x_j)\theta_{jk}$ for all (j, k) with $j \in N$ and $k \in K_j$.

Step 2. Linearization: Substitute a continuous variable for each distinct nonlinear term in the products $\otimes_{j \in J} \mathbf{x}^j \otimes \mathbf{x}$ and $\otimes_{j \in J} \mathbf{x}^j \otimes \mathbf{y}$ present in the reformulation. Denote the linearized vectors as $\{\otimes_{j \in J} \mathbf{x}^j \otimes \mathbf{x}\}_L$ and $\{\otimes_{j \in J} \mathbf{x}^j \otimes \mathbf{y}\}_L$ respectively, with the newly defined variables in these two sets given by $\mathbf{w}$ and $\mathbf{v}$. Call the resulting polyhedral set in the variables $(\mathbf{x}, \mathbf{y}, \mathbf{w}, \mathbf{v})$ as $\mathbf{X}_d$.

Three comments are warranted. First, the nonnegativity of the $\prod_{j \in J} k_j$ functions found in $\otimes_{j \in J} C_j \mathbf{x}^j$, and used in the reformulation step, is due to LIP Property 1. Second, for each $J \subseteq N$ with $|J| = d$, the reformulation does not multiply the products $\otimes_{j \in J} C_j \mathbf{x}^j$ by any $C_k \mathbf{x}^k \geq \mathbf{0}$ having $k \in J$ since the resulting linearized inequalities would be implied by $\mathbf{X}_d$. This is due to LIP Property 3 reducing such (nontrivial) multiplications to $\otimes_{j \in J} C_j \mathbf{x}^j \geq \mathbf{0}$. For $d \leq n - 1$, these inequalities can be shown implied by any products of the form $\otimes_{j \in J \cup k} C_j \mathbf{x}^j \geq \mathbf{0}$ for which $k \notin J$, with the linearized version of these latter products found within $\mathbf{X}_d$. For $d = n$, all $\prod_{j \in N} k_j$ such inequalities with $J = N$ are enforced. Third, the set $\mathbf{X}_n$ does not need to include these $\prod_{j \in N} k_j$ inequalities $\otimes_{j \in N} C_j \mathbf{x}^j \geq \mathbf{0}$ if there exist any continuous variables $\mathbf{y}$ within the problem since the multiplication of such products with the inequalities $\mathbf{L} \leq \mathbf{y} \leq \mathbf{U}$ would deem them redundant. (Note the similarity of the last two comments to the redundancy of certain nonnegative

functional factors $\prod_{j \in J_1} x_j \prod_{j \in J \setminus J_1} (1 - x_j) \geq 0$ for the mixed-binary case when $J_1 \subseteq J \subseteq N$.)

The RLT hierarchy for mixed-discrete programs is a generalization of that for mixed-binary problems both in theory and in construction. Paralleling the mixed-binary case, two important theoretical properties hold true. First, for each $d \in N$, every feasible $(\mathbf{x}, \mathbf{y}, \mathbf{w}, \mathbf{v})$ to $\mathbf{X}_d$ with $x_j \in S_j$ and $\{\mathbf{x}^j\}_L = \mathbf{x}^j$ for all $j \in N$ will have the variables $\mathbf{w}$ and $\mathbf{v}$ equal to their intended products. This gives a hierarchy of equivalent mixed-integer linear reformulations of $\mathbf{X}$ in Equation (1) for general sets S_j having $k_j \geq 2$. Second, for each $d \in \{0, 1, \dots, n\}$, letting

$$P_{(\mathbf{x}, \mathbf{y})}(\mathbf{X}_d) \equiv \{(\mathbf{x}, \mathbf{y}) : (\mathbf{x}, \mathbf{y}, \mathbf{w}, \mathbf{v}) \in \mathbf{X}_d \text{ for some } (\mathbf{w}, \mathbf{v})\}$$

denote the projection of the set $\mathbf{X}_d$ onto the space of the variables $(\mathbf{x}, \mathbf{y})$ as in Equation (2), it also follows that

$$P_{(\mathbf{x}, \mathbf{y})}(\mathbf{X}_0) \subseteq P_{(\mathbf{x}, \mathbf{y})}(\mathbf{X}_1) \subseteq \dots \subseteq P_{(\mathbf{x}, \mathbf{y})}(\mathbf{X}_n) = \text{conv}(\mathbf{X}),$$

as in Equation (3). Hence, the highest level provides an explicit algebraic representation of the convex hull of feasible solutions in the higher-dimensional space $\mathbf{X}_n$.

A subtle difference between the mixed-binary and mixed-discrete cases is that the latter includes the restrictions $C_j \{\mathbf{x}^j\}_L \geq \mathbf{0}$ for all $j \in N$, linearized from Equation (5), within $\mathbf{X}_0$. This has $\mathbf{X}_0$ containing variables $\mathbf{w}$, so that it lies in a different variable space than $P_{(\mathbf{x}, \mathbf{y})}(\mathbf{X}_0)$. Hence, unlike Equation (3), $\mathbf{X}_0 \neq P_{(\mathbf{x}, \mathbf{y})}(\mathbf{X}_0)$ for the discrete case. However, as the projection of the inequalities $C_j \{\mathbf{x}^j\}_L \geq \mathbf{0}$ for all $j \in N$ collectively reduce to $\theta_{j1} \leq x_j \leq \theta_{jk_j}$ for all $j \in N$, the set $P_{(\mathbf{x}, \mathbf{y})}(\mathbf{X}_0)$ is $\mathbf{X}$ of Equation (5) without the inequalities $C_j \mathbf{x}^j \geq \mathbf{0}$ for all $j \in N$, and with the $x_j \in S_j$ restrictions replaced by $\theta_{j1} \leq x_j \leq \theta_{jk_j}$ for all $j \in N$. This is the usual continuous relaxation of such a mixed-discrete set.

Relative to construction, the mixed-discrete hierarchy reduces to the mixed-binary hierarchy when the sets S_j , for all $j \in N$, in the former are restricted to have

$k_j = 2$ (so that $K_j = \{1, 2\}$) with $\theta_{j1} = 0$ and $\theta_{j2} = 1$. With this restriction, each $C_j \mathbf{x}^j$ reduces to $1 - x_j$ and x_j , and the substitution $L_{jk}(x_j)x_j = L_{jk}(x_j)\theta_{jk}$ for all (j, k) with $j \in N$ and $k \in K_j$ in the reformulation step becomes $x_j^2 = x_j$ for all $j \in N$. The linearization step has the replacement of $\mathbf{w}$ for $\{\otimes_{j \in J} \mathbf{x}^j \otimes \mathbf{x}\}_L$ and $\mathbf{v}$ for $\{\otimes_{j \in J} \mathbf{x}^j \otimes \mathbf{y}\}_L$ reducing to the simpler substitutions $w_J = \prod_{j \in J} x_j$ and $v_{Jk} = y_k \prod_{j \in J} x_j$ found in the mixed-binary case.

The example below illustrates the increasing strength of the hierarchical levels.

Example 3. Let $\mathbf{X}$ of (5) be given by $\mathbf{X} = \{(x_1, x_2) \in \mathbb{R}^2 : 2x_1 - 2x_2 \geq -3, -2x_1 + 2x_2 \geq -3, -2x_1 - 2x_2 \geq -11, 2x_1 + 2x_2 \geq 5, C_j \mathbf{x}^j \geq \mathbf{0} \text{ for } j \in N = \{1, 2\}, x_1 \in S_1 = \{1, 2, 3\}, x_2 \in S_2 = \{1, 2, 3\}, \text{ with } C_j \mathbf{x}^j \geq \mathbf{0} \text{ expressed as}$

$$\begin{bmatrix} 3 & -\frac{5}{2} & \frac{1}{2} \\ -3 & 4 & -1 \\ 1 & -\frac{3}{2} & \frac{1}{2} \end{bmatrix} \begin{pmatrix} 1 \\ x_j \\ x_j^2 \end{pmatrix} \geq \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}$$

for $j = 1, 2$.

Then $S_j = \{1, 2, 3\}$ with $k_j = 3$ for $j \in N = \{1, 2\}$, and there exist no continuous variables $\mathbf{y}$. The level-0 RLT projected onto the space of the variables (x_1, x_2) is the region defined in Fig. 2 by the solid lines, with the eight extreme points: $(1, \frac{3}{2}), (1, \frac{5}{2}), (\frac{3}{2}, 3), (\frac{5}{2}, 3), (3, \frac{5}{2}), (3, \frac{3}{2}), (\frac{5}{2}, 1), (\frac{3}{2}, 1)$. The projected level-1 RLT is defined by the dashed lines, with the eight extreme points: $(1, 2), (\frac{4}{3}, \frac{8}{3}), (2, 3), (\frac{8}{3}, \frac{8}{3}), (3, 2), (\frac{8}{3}, \frac{4}{3}), (2, 1), (\frac{4}{3}, \frac{4}{3})$. The projected level-2 RLT is the shaded region with the four extreme points:

$(1, 2), (2, 3), (3, 2), (2, 1)$, which is the convex hull of feasible points.

As with the mixed-binary case, partial convex hull characterizations can be constructed for the mixed-discrete case. The variable x_2 can be treated as continuous by considering it to lie within $\mathbf{y}$. Then the $C_2 \mathbf{x}^2 \geq \mathbf{0}$ restrictions simplify to $1 \leq x_2 \leq 3$. The projected level-0 RLT remains unchanged, and the projected level-1 RLT gives $\text{conv}(\mathbf{X} \cap x_1 \in S_1)$. Figure 3 gives both projected regions, with level-0 defined by the solid lines and level-1 depicted by the shaded region. The six extreme points to this shaded region are $(1, \frac{3}{2}), (1, \frac{5}{2}), (2, 3), (3, \frac{5}{2}), (3, \frac{3}{2}), (2, 1)$, with each such point having $x_1 \in S_1$.

The RLT constructs for mixed-discrete programs are sufficiently flexible to allow enhancements similar to those for the mixed-binary case. Mixed-discrete *polynomial* programs that are linear in the continuous variables $\mathbf{y}$ for fixed realizations of $\mathbf{x}$ can be readily handled by the RLT. In this case, a hierarchy of polyhedral approximations leading to the convex hull representation is again available, but each hierarchical level d must be large enough to accommodate the nonlinear terms. Problems having products of the continuous variables $\mathbf{y}$ can also be linearized; however, as with the mixed-binary case, convex hull representations are not necessarily available.

The conditional logic arguments [5,6] that tighten inequalities for mixed-binary problems are also applicable to mixed-discrete

Figure 2. Projected RLT regions for x_1, x_2 discrete.

Figure 3. Projected RLT region for x_1 discrete and x_2 continuous.

programs, in a modified form. Again, the nonlinear nature of the constructed inequalities affords additional strength. To see this, consider a discrete variable x_j that can realize values in the set $S_j \equiv \{\theta_{j1}, \dots, \theta_{jk_j}\}$. Multiplication of any inequality $\alpha x + \beta y \geq b$ defining $\mathbf{X}$ in Equation (5) with the LIP $L_{jt}(x_j)$ for some $t \in K_j$ yields the quadratic inequality

$$L_{jt}(x_j)[\alpha x + \beta y - b] \geq 0.$$

Now, suppose the “condition” that $x_j = \theta_{jt}$ implies $\alpha x + \beta y \geq b'$ for $b' > b$ holds true. Then this inequality can be “logically” modified to

$$L_{jt}(x_j)[\alpha x + \beta y - b'] \geq 0,$$

which affords a strengthened form in the RLT linearization step. This strengthened inequality follows since $L_{jt}(x_j) = 0$ if $x_j \neq \theta_{jt}$ by LIP Property 1 of the section titled “Lagrange Interpolating Polynomials,” and $L_{jt}(x_j) = 1$ with $\alpha x + \beta y - b' \geq 0$ if $x_j = \theta_{jt}$, also by Property 1.

ONGOING RESEARCH

The use of LIPs, embedded within an RLT framework, provides the theoretical foundation for generating tight polyhedral outer approximations and convex hull representations of mixed-discrete sets. Such representations exhibit considerable promise for more effectively solving combinatorial

optimization problems. Accompanying this promise, however, are theoretical and computational challenges that stem from the large linear programming representations generated at the different RLT levels. Explorations are beginning into the effective handling of these forms. To this author’s knowledge, no computational experience has yet been reported on using LIPs to solve mixed-discrete programs with general integer variables.

Based on the insights and lessons learned from studies on the mixed-binary RLT, four research directions arise. The RLT representations grow in size as progression is made up through the hierarchy. However, as noted for the mixed-binary case, even the weakest level-1 form provides very tight representations that tend to dominate alternate bounding mechanisms. Moreover, this form has an inherent, block-diagonal, decomposable structure. Preliminary studies show that these same two properties of strength and structure hold true for the discrete case. A research direction is to determine means for most effectively exploiting the level-1, mixed-discrete forms.

A second promising direction is to reduce the sizes of the higher-dimensional RLT representations by recasting them onto lower-dimensional spaces through the use of projection operators. Given a mixed-discrete problem, since the highest level RLT form provides a description of the convex hull, each valid linear inequality in the original problem space must be theoretically computable via a projection.

Of course, obtaining all facets for a given problem reduces to enumerating the extreme directions of a suitably defined projection cone. The identification of all such directions is the outstanding challenge, both for general problem classes and specific instances having special structures. Efforts in this vein are underway, with initial results in Adams and Henry [22] and Henry [23]. Notably, RLT forms other than the highest level can also be used to motivate tight approximations in the original variable space.

A third direction, which closely relates to the projections mentioned above, is the generation of cutting planes. Partial convex hull representations play a critical role here, as they promote considerably smaller problems than the full RLT forms. Specifically, suppose some linear function in the discrete variables $\mathbf{x}$ and continuous variables $\mathbf{y}$ is optimized as a linear program over the set $P_{(\mathbf{x},\mathbf{y})}(\mathbf{X}_0)$ which, as described earlier, is $\mathbf{X}$ of Equation (5) without the inequalities $C_j \mathbf{x}^j \geq \mathbf{0}$ for all $j \in N$, and with the $x_j \in S_j$ restrictions replaced by $\theta_{j1} \leq x_j \leq \theta_{jk_j}$ for all $j \in N$. Further, suppose that the computed extreme point optimal $(\hat{\mathbf{x}}, \hat{\mathbf{y}})$ to $P_{(\mathbf{x},\mathbf{y})}(\mathbf{X}_0)$ does not have $\hat{x}_j \in S_j$ for all $j \in N$ (since otherwise $(\hat{\mathbf{x}}, \hat{\mathbf{y}})$ would solve the mixed-discrete program). Select any $t \in N$ such that $\hat{x}_t \notin S_t$, and consider a modified version of $P_{(\mathbf{x},\mathbf{y})}(\mathbf{X}_0)$, say $\mathbf{X}'$, that is obtained by treating all variables x_j with $j \in N \setminus \{t\}$ as continuous and *only* the variable x_t as discrete. This is accomplished by inserting the k_t linear inequalities $C_t \{\mathbf{x}^t\}_L \geq \mathbf{0}$ within $P_{(\mathbf{x},\mathbf{y})}(\mathbf{X}_0)$ to replace the $\theta_{t1} \leq x_t \leq \theta_{tk_t}$ bounding restrictions, and by treating all remaining variables $j \in N \setminus \{t\}$ to lie within $\mathbf{y}$. Now, calling the associated level-1 RLT form of $\mathbf{X}'$ as $\mathbf{X}'_1$, since $P_{(\mathbf{x},\mathbf{y})}(\mathbf{X}'_1) = \text{conv}(\mathbf{X} \cap x_t \in S_t)$, the point $(\hat{\mathbf{x}}, \hat{\mathbf{y}})$ cannot be feasible to $P_{(\mathbf{x},\mathbf{y})}(\mathbf{X}'_1)$. Then a linear inequality, or cutting plane, in $(\mathbf{x}, \mathbf{y})$ which is valid for $P_{(\mathbf{x},\mathbf{y})}(\mathbf{X}_0)$ and separates the set $P_{(\mathbf{x},\mathbf{y})}(\mathbf{X}_0)$ from the point $(\hat{\mathbf{x}}, \hat{\mathbf{y}})$ can be generated as a surrogate of the constraints defining $\mathbf{X}'_1$. This “projected” cut can then be included within the inequalities defining $P_{(\mathbf{x},\mathbf{y})}(\mathbf{X}_0)$, and the linear problem resolved with this additional restriction included in $P_{(\mathbf{x},\mathbf{y})}(\mathbf{X}_0)$.

There is a great deal of flexibility in computing cutting planes. The specific form of the cut generated to separate $(\hat{\mathbf{x}}, \hat{\mathbf{y}})$ from $P_{(\mathbf{x},\mathbf{y})}(\mathbf{X}_0)$

depends on the choice of surrogate multipliers. In fact, many such cuts can be derived. The selection of the index $t \in N$ having $\hat{x}_t \notin S_t$ can also be significant. If desired, more than one fractional variable can be chosen, so that the cut generation employs an explicit representation of $\text{conv}(\mathbf{X} \cap x_j \in S_j \forall j \in J)$, for some set $J \subseteq N$ having $|J| \geq 2$. The trade-off here is a tightening of the cuts at the expense of larger, level- $|J|$ RLT forms. Also, exploitation of mathematical structures to obtain simpler RLT forms appears promising. As mentioned earlier, a successful implementation of the special case dealing with mixed-binary programs is found in Balas *et al.* [10].

A fourth direction is to use the convex hull representations available at the highest level as a theoretical tool for making inferences about optimal solutions to mixed-discrete programs from optimal solutions to linear programming relaxations. From the section titled “RLT for Mixed-Binary Sets,” the works [11,12] identified conditions under which variables realizing binary values in an optimal solution to the continuous relaxation of a binary program will persist in retaining these same values in an optimal solution to the discrete problem. This was accomplished using inductive arguments that implicitly climb the RLT hierarchical ladder, without explicitly writing these formulations. Similar approaches may prove fruitful for the mixed-discrete case.

INTRODUCTION

Consider a general multicriteria decision-making (MCDM) problem that can be formulated as follows:

$$\begin{aligned} \text{"Max"} \quad & z = f(x) = (f_1(x), \dots, f_p(x)) \quad (1) \\ \text{s.t.} \quad & x \in X \end{aligned}$$

where x is the *decision vector*, $X \subseteq \mathbb{R}^n$ is the *feasible decision space*, $f_j(\cdot)$ is the j th *criterion (objective) function*, and z is the *criterion vector*. The above formulation uses the decision space representation of an MCDM problem. One can also formulate MCDM problems in the criterion space as follows:

$$\begin{aligned} \text{"Max"} \quad & \{z_1, \dots, z_p\} \quad (2) \\ \text{s.t.} \quad & z \in Z \end{aligned}$$

where $Z = \{z \in \mathbb{R}^p : z = f(x) : x \in X\}$ is called the (*feasible*) *criterion space*. That is, Z is the image of the feasible decision set (X) in the criterion space. Throughout the text, we refer to both x and z as the solutions (alternatives) of the MCDM problem.

A classification of the MCDM problems can be made based on whether the solutions (alternatives) are explicitly or implicitly defined. Problems where a finite set of alternatives is explicitly given are called *multiple-criteria evaluation problems* (or *multicriteria evaluation problems*) and problems where the set of alternatives is implicitly defined by constraints are called *multiple-criteria design problems* or *multiple-objective (mathematical programming) problems* (MOPs) [1]. When

the problem considered is an MOP, $X \in \mathbb{R}^n$ can be discrete or continuous.

Note that the maximization of a vector in models 1 and 2 is not a well-defined operator. Therefore, solving an MCDM model may refer to different things depending on the context. Most MCDM approaches try to identify the best alternative, that is, to find the alternative that is most preferred by the decision maker (DM). Some other cases are also possible. For example, three kinds of *problematiques* are reported to be generally used in practice in order to support DMs in multicriteria evaluation problems [2, 3]. These are as follows:

1. identify the best alternative or a small subset of good alternatives;
2. rank the alternatives from the best to the worst;
3. classify/sort the alternatives into predefined homogeneous groups.

If the MCDM problem is an MOP, that is, the set of solutions is implicitly defined by constraints, the number of solutions can be infinite (in the continuous case) or prohibitively large (in the discrete case); hence, the ranking and sorting problematiques are not typically considered. In such cases, one may want to identify the best alternative or a small subset of good alternatives.

Unless there is a single alternative that is better than the others in terms of all the criteria, which typically is not the case when there are conflicting objectives, the need to distinguish different solutions from each other makes some information on the DM's preferences necessary. This makes MCDM theory closely connected to the theory on preference relations and utility. Basic notation and definitions used in the theory of preference relations are provided in the next section.

In this study, we provide a review of the literature on interactive MCDM approaches that use convex cones as a means of representing the DM's preference structure. In the next section, we discuss the relation

between preference relations and value (utility) functions. Specifically, we provide the assumptions made on the DM's underlying preference relation by the MCDM solution methods using the convex cones approach. In the section titled "Convex Cones and Polyhedra," we cover the basic theory on the convex cones approach and show how the cones can be used to obtain the best solution in a given set. We also discuss a related concept: the use of polyhedra whose vertices are the cone generators in MCDM ranking or sorting problems. We then provide a review of the MCDM approaches that use the convex cones and we conclude the discussion in the section titled "Conclusion."

PREFERENCE RELATIONS AND VALUE FUNCTIONS

We first define and discuss the properties of a weak preference relation, denoted by $\preceq$, which completely characterizes the preference model in the criterion space. Next, we introduce the term *rational preference* along with its underlying properties and discuss the relation between preference relations and value functions. We then provide the assumptions on the DM's preference relation that allow us to use convex cones in MCDM approaches.

For two alternatives z^1 and z^2 , the statement $z^1 \preceq z^2$ is used to symbolize that z^2 is *weakly preferred* to z^1 .

Definition 1 Given a relation of weak preference, the corresponding relations of strict preference and indifference are defined as follows:

$$\begin{aligned} z^1 < z^2 & (z^2 \text{ is strictly preferred to } z^1) \\ \iff (z^1 \preceq z^2 \text{ and not } z^2 \preceq z^1) \\ z^1 \sim z^2 & (z^2 \text{ is indifferent to } z^1) \\ \iff (z^1 \preceq z^2 \text{ and } z^2 \preceq z^1). \end{aligned}$$

We now define some properties for a preference relation.

Definition 2 A preference relation $\preceq$ is complete if either $z^1 \preceq z^2$ or $z^2 \preceq z^1$, for all $z^1, z^2 \in Z$.

A preference relation $\preceq$ is transitive if $(z^1 \preceq z^2 \text{ and } z^2 \preceq z^3) \Rightarrow z^1 \preceq z^3$, for all $z^1, z^2, z^3 \in Z$.

Preference relation $<$ satisfies strict monotonicity (SM) if $z^1 < z^2$ then $z^1 < z^2$, for all $z^1, z^2 \in Z$.

The relation $\preceq$ is called a *rational preference relation* if it is complete, transitive, and its strict part ($<$) is strictly monotonic. On the basis of rational preferences, we can define (rational) dominance, which is the intersection relation of all rational preference relations [4].

Definition 3 For any two alternatives z^1 and z^2 , $z^1 <_r z^2$ (z^2 (rationally) dominates z^1) if $z^1_i \leq z^2_i$, for all $i \in \{1, 2, \dots, p\}$ where at least one strict inequality holds. $z^1 \preceq_r z^2$ (z^2 weakly dominates z^1) if $z^1_i \leq z^2_i$, for all $i \in \{1, 2, \dots, p\}$.

Having defined these preference relations, we can now discuss their relation with value functions.

Definition 4 The preference relation $\preceq$ is said to be represented by a value function $v(\cdot)$ if $\forall z^1, z^2, v(z^1) \leq v(z^2)$ if and only if $z^1 \preceq z^2$.

A preference relation is not necessarily representable by a value function. However, one can derive the conditions under which a preference relation is representable by a specified form of value function. We provide later one of the well-known results on representability by Debreu [5, 6].

Definition 5 A set A is closed if and only if it contains all of its limit points. A preference relation is continuous if for all $z \in Z$, $\{y \in Z \mid y \preceq z\}$ and $\{y \in Z \mid z \preceq y\}$ are closed.

The well-known representation theorem by Debreu [5, 6] is as follows.

Theorem 1 If a preference relation on a set $Z \subseteq \mathbb{R}^p$ is complete, transitive, and continuous, then it is representable by a continuous utility (value) function.

In an MCDM problem, if the DM has a rational preference relation representable by a value function, then this function is strictly increasing. Further structural assumptions on the value function imply further assumptions on the underlying preference relation of the DM.

MCDM solution strategies under the *value maximization approach* assume that the DM's preferences are representable by an underlying value function ($v : Z \rightarrow \mathbb{R}$) and involve maximizing this value function. Different forms of value functions have been studied such as linear [7, 8], quasiconcave [9], and monotonically increasing [10]. There are also algorithms for partially ranking [11] or sorting [12] alternatives based on an implicit quasiconcave value function assumption.

The MCDM approaches can also be categorized based on when the information is taken from the DM as follows [3], Chapter 16:

- *Methods based on the prior articulation of preferences:* In such methods, the preference information from the DM is taken at the beginning.
- *Methods based on the progressive articulation of preferences:* These approaches are called *interactive approaches*. In such methods, we iteratively reduce the solution space and approach the best solution (or a subset of good solutions), eliciting preference information from the DM at each iteration. Interactive value maximization strategies assume an implicit value function and employ an interactive search process that makes use of the structural assumptions on the value function (see Refs [13] and [14] for two reviews).
- *Methods based on the posterior articulation of preferences:* These methods try to find a good approximation of the non-dominated frontier and present it to the DM.

Preference information can be gathered in different forms. The DM can be asked to provide pairwise comparisons of alternatives, provide reference points [15], reference directions, trade-offs, information on strength of preferences [16], and so on.

A review of the literature on interactive MCDM approaches using convex cones as a means of representing the DM's preference structure is provided in this study. A convex cone is a convex polyhedral set in the objective function (criterion) space that contains solutions that are less preferred by the DM than a given set of solutions [9].

In most of the approaches using convex cones, the DM's preference model is assumed to be representable by a value function that is (strictly) quasiconcave and increasing. A function $g(\cdot)$ is strictly quasiconcave if for all $z^1, z^2 : z^1 \neq z^2$, and $\alpha \in [0, 1]$, we have $g(\alpha z^1 + (1 - \alpha)z^2) > \min\{g(z^1), g(z^2)\}$. Similarly, g is quasiconcave if $g(\alpha z^1 + (1 - \alpha)z^2) \geq \min\{g(z^1), g(z^2)\}$.

The quasiconcavity assumption of the DM's value function implies that the DM's preference relation is rational (i.e., complete, transitive, and strictly monotonic) with an additional convexity assumption.

Definition 6 A preference relation $\leq$ satisfies (weak) convexity if for all $z^1, z^2, z^3 \in Z$, such that $z^1 \leq z^2$ and $z^3 \in (z^1, z^2]$, we have $z^1 \leq z^3$. ($z^3 \in (z^1, z^2]$ means that there exists a real $\alpha, 0 < \alpha \leq 1$ such that $z^3 = \alpha z^1 + (1 - \alpha)z^2$. That is, z^3 is a convex combination of z^1 and z^2 .)

The quasiconcavity assumption for the value function corresponds to requiring the indifference curves (contours) to be convex to the origin. This assumption is quite reasonable, as it corresponds to decreasing marginal rate of substitution (DMRS), which is a commonly accepted property underlying consumer preferences in economics literature [17]. As the name implies, *marginal rate of substitution* is the maximum amount of one good a consumer would be willing to give up in order to obtain an additional unit of another. The marginal rate of substitution between two goods usually depends on the amount of goods the consumer currently has. For example, consider a case where the consumer has two types of goods: Good 1 and Good 2. When the consumer has a large amount of Good 1 and a very small amount of Good 2, he or she would probably be willing to give up quite a large amount

of Good 1 (as he or she already has plenty) to obtain one more unit of Good 2 (as Good 2 is scarce). In the opposite case where the consumer has a small amount of Good 1 and plenty of Good 2, he or she would probably be willing to give up only a very small amount of Good 1 to obtain more of Good 2. This is called the *DMRS*. As seen in the example, DMRS implies that, as the consumption of one good increases and the other decreases, the consumer would be willing to give up smaller quantities of the latter in exchange of a further unit of the former [17].

CONVEX CONES AND POLYHEDRA

We now provide a review of relevant results and studies from the literature on the use of convex cones in solving MCDM problems.

Basic Theory

We start with a discussion of two studies by Korhonen *et al.* [9] and Hazen [18], who introduce the basic theoretical results underlying the convex cones approach in independent works. The two results slightly differ in the underlying assumptions; hence, we will consider them separately. The main difference is that, the first assumes that a value function exists, whereas the second one relaxes this assumption. We start with the first results by Ref. [9] and then provide the more general case that is given by Ref. [18].

Assuming an Implicit Value Function. Given a set of k vectors, such that $z^1, \dots, z^k \in \mathbb{R}^p$, and an increasing quasiconcave function $f(\cdot)$ defined on $\mathbb{R}^p$, such that $f(z^k) < f(z^i)$ for all $i \neq k$, the following definitions are made:

Definition 7 We define the cone $C(z^1, \dots, z^{k-1}; z^k)$, where $z^i : i \neq k$ are the upper generators and z^k is the lower generator as follows: $C(z^1, \dots, z^{k-1}; z^k) = \{z \mid z = z^k + \sum_{i=1}^{k-1} \mu_i (z^i - z^k), \mu_i \geq 0\}$. The cone-dominated region of $C(z^1, \dots, z^{k-1}; z^k)$ is denoted by $CD(z^1, \dots, z^{k-1}; z^k)$ and defined as follows: $CD(z^1, \dots, z^{k-1}; z^k) = \{z' \mid z' \leq z \text{ where } z \in C(z^1, \dots, z^{k-1}; z^k)\}$.

Lemma 1 For any $z \in C(z^1, \dots, z^{k-1}; z^k)$, $f(z) \leq f(z^k)$. Moreover, for any $z' \in CD(z^1, \dots, z^{k-1}; z^k)$, $f(z') \leq f(z^k)$.

Definition 8 We define the polyhedron spanned by the vectors $z^1, \dots, z^k$ as follows: $P(z^1, \dots, z^k) = \{z \mid z = \sum \mu_i z^i, \sum \mu_i = 1, \mu_i \geq 0 \text{ for all } i\}$. The upper side of $P(z^1, \dots, z^k)$ is denoted by $UP(z^1, \dots, z^k)$ and defined as follows: $UP(z^1, \dots, z^k) = \{z' \mid z \leq z', \text{ where } z \in P(z^1, \dots, z^k)\}$.

Lemma 2 For any $z \in P(z^1, \dots, z^k)$, $f(z^k) \leq f(z)$. Moreover, for any $z' \in UP(z^1, \dots, z^k)$, $f(z^k) \leq f(z')$.

Assume that we have k points such that $z^1, \dots, z^k \in \mathbb{R}^p$ and $z^k < z^i$ for all $i \neq k$, where $<$ is the DM's preference relation. We assume that $<$ is a rational preference relation. If the DM has a quasiconcave value function $f(\cdot)$, by Lemma 1, for any $z \in C(z^1, \dots, z^{k-1}; z^k)$, we have $f(z) \leq f(z^k)$, hence $z \leq z^k$. Moreover, for each point $z' : z' \leq z$, where $z \in C(z^1, \dots, z^{k-1}; z^k)$, $z' \leq z^k$, that is, the points in the cone-dominated region will be at most as preferred as z^k . We will call each such point $z' \in CD(z^1, \dots, z^{k-1}; z^k)$ *cone dominated*. Note that if we assume strict quasiconcavity, we have $z < z^k$ for $z \neq z^k$ and $z' < z^k$ for $z' \neq z^k$.

Similarly, by Lemma 2, for any $z \in P(z^1, \dots, z^{k-1}, z^k)$, $f(z^k) \leq f(z)$, hence $z^k \leq z$. Moreover, for each point, $z' : z \leq z'$, where $z \in P(z^1, \dots, z^k)$, $z^k \leq z'$, that is, the points lying on the upper side of the polyhedron spanned by the k points will be at least as preferred as the lower generator, z^k . If we assume strict quasiconcavity, we have $z^k < z$ and $z^k < z'$.

Figure 1 shows an example of a 2-point cone in $\mathbb{R}_+^2$. The thick solid line is the cone $C(z^1; z^2)$ and the area with diagonal gray lines is the cone-dominated region, $CD(z^1; z^2)$. The line segment between z^1 and z^2 is the polyhedron $P(z^1, z^2)$ and the region above this line segment is the upper side of the polyhedron, $UP(z^1, z^2)$.

Figure 2 shows an example of a 3-point cone in $\mathbb{R}_+^2$. The region filled with the diagonal lines is $C(z^2, z^3; z^1)$ and the gray region

Figure 1. Illustration of a 2-point cone in $\mathbb{R}^2_+$.

including the dark gray part and the diagonal lines is the cone-dominated region. We refer the reader to Fig. 1.b in Ref. [19] for an illustration of a 3-point cone in $\mathbb{R}^3$.

We will visualize the additional information implied by the quasiconcavity using an example. Recall that a quasiconcave value function implies the convexity assumption on the DM's preference relation. See Fig. 3 for the criteria space of a bicriteria example where two of the alternatives (z^1 and z^2) are seen. Suppose that the DM has a rational preference relation that can be represented by a value function and prefers z^2 to z^1 ($z^1 < z^2$). By SM, one can say that the points in region A are less preferred to z^1 . By convexity (quasiconcavity), we gain information about region B, which is cone dominated; hence, the points in that region are less preferred to z^1 .

Similarly, using monotonicity, we can conclude that any alternative in regions C and D are preferred to z^1 . As $z^1 < z^2$, transitivity ensures that the points in region E, which are vector dominating z^2 , are also preferred to z^1 . Using convexity (quasiconcavity), we are able to say that the points in region F are preferred to z^1 . Therefore, we gain information about regions F and B by assuming a quasiconcave value function. Observe that the amount of the additional information gained depends on the two alternatives selected. One line of research in convex cones theory in MCDM focuses on finding smart ways of selecting the sets of alternatives to ask the DM.

A more General Result. Hazen [18] discusses the same results by showing that consideration of explicit responses (preference information) in the presence of increasing quasiconcave utility yields a stronger order than the strict componentwise vector order ($<$). He directly works on the DM's preference relation defined over the set of alternatives, rather than assuming that it is represented by a value function.

Hazen assumes the following axioms for the DM's preference relation.

For a relation $<$:

1. Irreflexivity (I): not $z < z$, for all $z \in \mathbb{R}^p$.
2. Transitivity (T): ($z^1 < z^2$ and $z^2 < z^3$) $\Rightarrow$ $z^1 < z^3$, for all $z^1, z^2, z^3 \in \mathbb{R}^p$.
3. Strict monotonicity (SM): $z^1 < z^2 \Rightarrow z^1 < z^2$, for all $z^1, z^2 \in \mathbb{R}^p$.
4. Weak convexity (WC): $z^1 \leq z^2$ and $z^3 \in (z^1, z^2] \Rightarrow z^1 \leq z^3$, for all $z^1, z^2 \in \mathbb{R}^p$.
5. Convexity (C): $z^1 < z^2$ and $z^3 \in (z^1, z^2] \Rightarrow z^1 < z^3$, for all $z^1, z^2 \in \mathbb{R}^p$.
6. Preference data (PD): $z^1 < z^2 < \dots < z^m$ is provided by the DM.

Note that if the binary relation $<$ is representable by a value function, WC and convexity axioms correspond to the quasiconcavity and strict quasiconcavity of the function, respectively.

The PD axiom stands for the preference information provided by the DM, which is in the form of ranking m alternatives.

Hazen uses the concept of *unanimity order* that is analogous to the dominance concept in MCDM and defines it as follows.

Definition 9 Assume that the DM's preference relation satisfies I, T, SM, WC, C, and PD; and denote the set of binary relations satisfying these properties with B . The unanimity order with respect to B is the binary relation $<^*$ over outcome vectors x and y and defined as follows: $x <^* y \iff x < y$ for all $< \in B$.

Note that rational dominance is another unanimity order where B is the set of binary relations satisfying axioms reflexivity, transitivity, and SM.

Figure 2. Illustration of a 3-point cone in $\mathbb{R}^2_+$.

Figure 3. Using quasiconcavity.

The concept of unanimity order is important in MCDM, as it allows us to infer results without knowing the exact preference relation of the DM over the whole decision space. If we know that the preference relation of the DM satisfies a set of properties, any result that holds for the corresponding unanimity order will hold for the DM's preference relation.

Hazen's main result is the following theorem. Note that we changed the terminology to ensure consistency in presentation. (See the original paper for the original notation and the corresponding proof.)

Theorem 2 Suppose that $z^1, z^2, \dots, z^m : z^1 < z^2 < \dots < z^m$ are distinct elements of $\mathbb{R}^p$. Define the binary relation $<_m$ on $\mathbb{R}^p$ as follows: $x <_m y \iff x < y$ or $\exists j < m$ such that $x \in CD(z^{j+1}, z^{j+2}, \dots, z^m; z^j)$ and $y \in UP(z^{j+1}, z^{j+2}, \dots, z^m; x)$ and $y \neq x$. Then, $<^* = <_m$ unless $z^j \in P(z^{j+1}, z^{j+2}, \dots, z^m)$ for some j , in which case, $<^* = \mathbb{R}^p \times \mathbb{R}^p$ (in which case, the DM is inconsistent).

This theorem is valid for any case where we replace the componentwise strict vector partial order $<$ by any irreflexive conical order (see the original paper [18]). For an arbitrary vector space A , $<$ is a conical order if it is a binary relation on A represented by a convex cone K . That is, for all $x, y \in A$; $x < y \iff y - x \in K$.

Given PD $z^1 < z^2 < \dots < z^m$ and the assumptions on the DM's preference relation, Theorem 2 provides a necessary and

sufficient condition to conclude that a solution y is strictly preferred to solution x by the DM (without any further information): either $x < y$ or there is an alternative z^j in the given preference set, for which x lies in $CD(z^{j+1}, z^{j+2}, \dots, z^m; z^j)$ and y lies $UP(z^{j+1}, z^{j+2}, \dots, z^m; x)$.

When the DM is consistent, we have $x <^* y \iff x < y$ or $\exists j < m$, such that $x \in CD(z^{j+1}, z^{j+2}, \dots, z^m; z^j)$ and $y \in UP(z^{j+1}, z^{j+2}, \dots, z^m; x)$ and $y \neq x$.

It is easy to see that the sufficiency part of this proof holds as follows:

- If $x < y$, then $x <^* y$ (hence, $x < y$). This is trivial from SM.
- If $z \in CD(z^{j+1}, z^{j+2}, \dots, z^m; z^j)$ for some z^j , then $x < z^j$ by convexity, hence $x < z^{j+k}$ for $k = 1, \dots, m-j$ by transitivity. Therefore, any point $y : y \in UP(z^{j+1}, z^{j+2}, \dots, z^m; x)$ and $y \neq x$ will be strictly preferred to x because of convexity.

The necessary part of the statement is not obvious. By proving the necessary condition, Hazen shows that under given assumptions on the DM's preference relation, for any two solutions x and y , we cannot state that $x < y$; unless at least one of the two conditions is satisfied ($x < y$ or $\exists j < m$, such that $x \in CD(z^{j+1}, z^{j+2}, \dots, z^m; z^j)$ and $y \in UP(z^{j+1}, z^{j+2}, \dots, z^m; x)$ and $y \neq x$). This implies that under stated assumptions, by checking whether the conditions hold for two alternatives, a decision analyst will be making maximum use of the preference information available; if the conditions do not hold, he or she can be sure that it is not possible to conclude that one is preferred to the other without additional information.

This result is more general than the results provided in Lemmas 1 and 2, as the transitivity axiom allows indifference to be nontransitive, that is, it includes some cases where the DM's preference relation is not representable by a value function. Moreover, Theorem 2 applies to any irreflexive conical order. Therefore, Lemmas 1 and 2 are special cases of Theorem 2.

An Example. We will illustrate the results discussed so far using an example. We will show that under the same set of assumptions, the results provided in Lemmas 1 and 2 and Theorem 2 provide us the same information. In the example, we assume that the DM's preference structure is representable by a strictly quasiconcave value function and use the componentwise strict vector partial order $<$ for Theorem 2.

Figure 4 shows the criteria space of a bicriteria problem where the DM strictly prefers y to x , that is, $x < y$.

By Lemmas 1 and 2, we have the following:

1. $t \in CD(y; x)$, so $t < x$.
2. $k \in UP(y, x)$, hence $x < k$. We have $t < x < y$ and $t < x < k$. On the basis of the first ranking, one can generate $P(y, x, t)$.
3. Observing that $h \in P(y, x, t)$, we say that h is preferred to t . Therefore, we have $t < x < y, t < x < k$, and $t < h$.

According to Theorem 2, given $x < y$:

1. $t \in CD(y; x)$ and $x \in UP(y; t)$, hence $t < x$. Now we have $t < x < y$.
2. $x \in CD(y; x)$ and $k \in UP(y; x)$, hence $x < k$. We have $t < x < y$ and $t < x < k$.
3. Finally, $t \in CD(y; x)$ and $h \in UP(y; t)$, hence $t < h$. We obtain the same results: $t < x < y, t < x < k$, and $t < h$.

Operationalizing the Theory

In this section, we discuss how to operationalize the theory of convex cones. We would like to note here that the research seeking to operationalize the convex preference cone ideas originated from the team Korhonen, Wallenius, and Zionts, and their students and coworkers.

Checking Cone Dominance. The MCDM methods using convex cones gather preference information from the DM, usually in terms of pairwise comparisons. Using this information, more information is extracted about the other feasible alternatives that are not in the preference subset the DM provided.

Figure 4. Example case.

Given preference information, one can generate cones and check for each candidate point whether it is in a cone-dominated region. If the objective is finding the best alternative out of a set, the cone-dominated alternatives can be eliminated from further consideration. If we have a ranking or sorting problem, the information that an alternative is inside or in the upper side of the corresponding polyhedron is also useful. Therefore, one can also check the status of an alternative with respect to the generated polyhedra based on the preference information.

We can perform these checks using linear programming (LP) problems as follows.

Suppose that we want to check whether alternative z is dominated by $C(z^1, \dots, z^{k-1}; z^k)$. Then, we solve the following LP:

$$\begin{aligned}
 & \text{Max } \epsilon & (LP_1) \\
 & \text{s.t. } \sum_{i=1}^{k-1} \mu_i (z^k - z^i) - \epsilon \geq z - z^k \\
 & \mu_i \geq 0 \text{ for } i = 1, \dots, k-1.
 \end{aligned}$$

Let us rewrite the first constraint set as follows: $z^k + \sum_{i=1}^{k-1} \mu_i (z^k - z^i) \geq z + \epsilon$. For each feasible μ_i value, the left-hand side of the constraint corresponds to a point in the cone. If z is not dominated by any of the points in the cone, the maximum value that ϵ can take should be negative. Otherwise, if $\epsilon^* \geq 0$, the first constraint set implies $z^k + \sum_{i=1}^{k-1} \mu_i (z^k - z^i) \geq z$. Then, for any nondecreasing quasiconcave function $f(\cdot)$, we have $f\left(z^k + \sum_{i=1}^{k-1} \mu_i (z^k - z^i)\right) \geq f(z)$. That is, z is at most as preferred as a point in the cone, that is, $z \in CD(z^1, \dots, z^{k-1}; z^k)$ and $f(z^k) \geq f(z)$ by Lemma 1.

To check whether $x \in UP(z^1, \dots, z^k)$, we solve the following LP:

$$\begin{aligned}
 & \text{Max } \epsilon & (LP_2) \\
 & \text{s.t. } \sum_{i=1}^k \mu_i z^i + \epsilon \leq x \\
 & \sum_{i=1}^k \mu_i = 1 \\
 & \mu_i \geq 0 \text{ for } i = 1, \dots, k.
 \end{aligned}$$

One can see that if $\epsilon^* \geq 0$, then $x \in UP(z^1, \dots, z^k)$.

In each iteration, we gain new information leading to new cones and polyhedra.

Tree Representation of Preferences and Size of Cones. Interactive approaches are based on gathering preference information from the DM throughout the process. Hence, such algorithms must keep track of the preference information gathered so far and generate the corresponding cones. A tree representation for preferences is suggested for this purpose in Ref. [20]. An example tree is given in Fig. 5, where each node represents an alternative and each arc represents the preference relation between these alternatives. Using the tree representation, it is possible to identify all distinct cones and polyhedra that can be generated, given preference information.

Note that the size of each cone as well as the number of total cones generated will affect the number of alternatives eliminated by the cones; hence, the amount of information required from the DM. The computational time will also be affected. Different strategies can be used as follows:

- One might choose to generate all the possible cones with maximum number of generators. That is, for each alternative that is a candidate to be a lower generator (less preferred to at least one solution in the tree), one can generate a cone using all the alternatives preferred to that alternative as the upper generators. By doing so, one will be making maximum use of the information provided by the DM and hence less information is required from the DM [9, 21]. In the example given in Fig. 5, this corresponds to generating $C(z^1, z^2, z^3, z^4, z^5; z^6)$, $C(z^1, z^2, z^3, z^4; z^5)$, and $C(z^1, z^2; z^3)$. This is called the *minimal set of cones*.
- As the earlier method may be cumbersome and may result in high computational effort, one might choose to generate smaller cones [9, 20]. In the literature, in most cases, only 2-point cones are used. In the example case in Fig. 5, the distinct 2-point

Figure 5. Tree representation.

cones are $C(z^1; z^3)$, $C(z^2; z^3)$, $C(z^3; z^5)$, $C(z^4; z^5)$, and $C(z^5; z^6)$. Note that it is also possible to generate more 2-point cones using transitivity: for example, $C(z^1; z^5)$, $C(z^1; z^6)$, $C(z^2; z^5)$, and $C(z^2; z^6)$. Korhonen *et al.* [9] report that in their experiments, the computation time saved in using 2-point cones instead of the minimal set of cones was minimal and suggest using the minimal set of cones. The use of cones with the most number of generators possible is suggested also in Ref. [19] owing to the decrease in the preference information required from the DM in that case.

Selecting the Candidate Solutions. Another issue to be considered in any interactive algorithm using convex cones is selecting the candidate solutions to be asked to the DM. The method used to select the alternatives depends on the characteristics of the problem. There are studies that use an estimated value function in an effort to select good candidates [9]. At each iteration, the parameters of the value function are updated and a solution that maximizes this value function is found and the DM is asked to compare this solution with its adjacent efficient alternatives (for an alternative z in the criterion space, adjacent efficient alternatives are the ones whose convex combinations with z are not dominated

by any other convex combination generated by the rest of the alternatives). There are also studies selecting the candidates based on their distance to an ideal point [22].

Interaction Type. The interaction type refers to the type of the questions asked to the DM.

In the solution frameworks designed to select the best alternative, the DM is usually asked for pairwise comparisons of alternatives. Other strategies are also possible such as providing the DM with m alternatives and asking him or her to select the best/worst alternative in the set or rank these alternatives.

In the solution frameworks designed for sorting alternatives, the DM can also be asked to assign some alternatives to the pre-determined groups. These alternatives are then used to generate cones and polyhedra.

Related Works in Literature

Many interactive MCDM methods using convex cones are proposed in the literature. Although not as common as convex cones, polyhedra are also used in sorting and partial ranking. The studies mainly differ in terms of the nature of the problem and the nature of the solution procedure; that is, based on the way to elicit the preference information, the way to select the alternatives that will be presented to the DM for information gathering, and the size of the generated cones.

The first problems considered are mostly multicriteria evaluation problems, where there is a finite set of alternatives. A series of papers that extend the application of convex cones to other problem types, for example, multicriteria linear problems (MCLP), multicriteria integer problems (MCIP), follow. There are also studies on increasing the efficiency of the solution procedures by finding ways to increase the region eliminated by cones and determining the number of the cone generators to be used. Recently, there has been an interest in using convex cones and polyhedra to sort and partially rank a finite set of alternatives.

We now review these applications of convex cones and polyhedra reported so far for MCDM problems.

Korhonen *et al.* [9] design an interactive algorithm for finding the best alternative in multicriteria evaluation problems. They use convex cones to represent the preference structure. They generate cones and eliminate the alternatives that are inferior to these cones. By doing so, they successively restrict the solution space and try to obtain the best alternative after a number of iterations. In order to determine the alternatives to be asked to the DM, they use a composite linear value function of the form $\sum \delta_j x_{ij}$, where $\delta_j > 0$ are multipliers and x_{ij} is the performance score of alternative i in criterion j . They find the alternative that maximizes this function and ask the DM to compare it with other selected alternatives (the adjacent efficient alternatives). They start with an arbitrary set of multipliers and use the DM's responses to update the (feasible) set of multipliers. Note that this method approximates a nonlinear value function by a composite linear value function; hence, it is possible that there are no set of multipliers consistent with the DM's preferences. This is handled by deleting the restriction on multipliers that correspond to the oldest information from the DM. In the proposed algorithm, the information from the DM is gathered in terms of pairwise comparisons. The authors conduct experiments and report statistics on the number of pairwise judgements the DM has to make for various problem sizes. They first try generating all the cones and then repeat the experiments using only 2-point cones. On the basis of the results, they conclude that the savings in the computational time when one is using only 2-point cones does not justify the increase the judgements DM has to make and hence suggest generating the minimal set of cones.

A few variations of the above algorithm is proposed by Köksalan *et al.* [23], Köksalan and Taner [24], and Köksalan and Sagala [25]. These studies address the same problem as in Ref. [9] and propose improvements in the solution algorithm. They suggest using dummy alternatives as one of the cone generators in order to increase the region eliminated by the convex cones. They discuss different ways to generate and select appropriate dummy alternatives. The authors report

improvements in results compared to the algorithm used in Ref. [9] in terms of the total number of pairwise comparisons required to find the best alternative. In Ref. [25], which generalizes the results of the previous two papers [23, 24], two dummy alternatives are used simultaneously, one of which is (hopefully) less preferred to a real alternative, so that it can be used as an upper generator of the cone. The other dummy alternative is generated as a potential lower generator. The dummy points are selected with the help of an estimated value function that is updated at each iteration.

Malakooti [26] also discusses different ways to select the cone generators as in Ref. [23], including the idea of using dummy alternatives to increase the area that is eliminated by the cone. He also discusses the use of local gradients, that is, trade-off information, at a point to eliminate worse alternatives and find better ones.

Ramesh *et al.* [20] study the underlying theory of the convex cones and the representation structure for the DM's preferences based on convex cones. They define rules to detect redundant cones, the cones that are already implied by other existing cones, in order to avoid unnecessary computations. They discuss two ways to represent the DM's preferences. The first representation scheme is an explicit representation, which is used in methods that use a single composite function of the multiple objectives. In these methods, the preferences are represented using linear inequalities on the weights of this composite function; thus, the set of feasible weights is successively reduced. The second one is based on the convex cones. They conclude that representation via cones is more accurate than representation via linear constraints on weights of the objectives. This is because by using a composite objective function, one fails to accurately represent nonlinear value functions. The authors conduct experiments on the use of convex cones in solving both multicriteria design [MCLP, MCIP (in the experiments bicriteria problems are solved)] and multicriteria evaluation problems and report the percentage of questions saved using convex cones.

Ramesh *et al.* [21] incorporate the convex cones representation method into the algorithm of Zionts and Wallenius [27] for multicriteria LP problems. The authors assume that the DM has a pseudoconcave value function. Convex cones are used to obtain an accurate and robust representation of the DM's preferences. The DM is asked for pairwise comparisons of alternatives, one of them is an alternative that maximizes a composite linear value function and the other is an adjacent efficient alternative. Only 2-point cones are generated.

Ramesh *et al.* [28] develop an algorithm for the MCIP, where the underlying value function of the DM is assumed to be pseudoconcave. They use the method previously proposed by Zionts and Wallenius [27] for MCLP in a branch and bound framework and use convex cones for the preference structure representation. The cones are used for fathoming candidate nodes in the branch and bound tree. They only generate 2-point cones and report computational results for bicriteria problems with up to 80 variables and 40 constraints.

Köksalan [22] proposes an interactive method using convex cones to identify and rank a most preferred subset of alternatives in multicriteria evaluation problems. The DM is asked for pairwise comparisons. Initially, candidate solutions are selected based on their distance to an ideal point and throughout the algorithm, new candidate solutions are generated using a weighted quadratic value function as in Ref. [23].

Taner and Köksalan [29] conduct an experimental study on how to determine the number of cone generators, select the cone generators, and determine the order of pairwise comparisons to ask the DM. They also propose an algorithm based on the results of the experiments. In the proposed algorithms, $m(m = 1, 2, \dots, 7)$ alternatives are selected by three methods, which use equal weighted linear, estimated linear, and quadratic value functions, respectively. Then, the least/most preferred alternative in the selected set is found by asking the DM a number of pairwise comparisons. On the basis of the preference information elicited

from the DM, all the possible cones are generated. They conclude that the version where $m = 3$ and the least preferred alternative is found provides the best results in terms of the average number of comparisons the DM has to make. They point out that the results of the experiments are not very conclusive; hence, a more elaborate and detailed study awaits further attention.

Prasad *et al.* [19] observe that in the computations, although most of the solutions are not cone dominated, quite a few of them are nearly cone dominated. Motivated by this observation, they introduce the concept of “near cone dominance” or “ p cone efficiency.” A p value is used to show how close an alternative is to being dominated by the generated cone. They suggest using this measure to choose the challengers of the incumbent that will be presented to the DM for pairwise comparison. That is, the alternatives are presented to the DM for comparison in an order based on how close they are to be inferior. This heuristic extension is suggested to accelerate the search by reducing preference information requirement. Another use of this idea is for early termination. That is, for an incumbent solution, the p cone efficiencies of its adjacent solutions are calculated and the algorithm is terminated if maximum of these p cone efficiencies is below a given threshold. They illustrate the idea by incorporating it within a solution framework for solving MOLP problems.

Ulu and Köksalan [12] propose interactive approaches to partition a set of discrete alternatives into acceptable and unacceptable sets. Assuming that the DM has a quasiconcave value function, they use the convex cones and polyhedra in a sorting algorithm. Note that the proposed sorting algorithm is for the special case where the number of classes is two, rather than for the general case with more than two classes.

Another study that includes a sorting approach based on convex cones is Fowler *et al.* [30]. They propose an evolutionary algorithm, a genetic algorithm, for MCDM problems assuming that the DM has a quasiconcave preference function. Genetic algorithm is a widely studied method for

finding heuristic solutions to NP-hard problems. In a genetic algorithm, the output is obtained by evolving an initial population of solutions through multiple generations by breeding and mutation. Hence, how the parents are selected becomes a critical issue to ensure offspring with good quality. The authors suggest partially sorting the population with the help of convex cones and polyhedra. The information taken from the DM is in terms of finding the best and worst in a given set of six solutions. Using this information, they generate four 2-point cones (consisting of the best as the upper generator and each of the other points except the worst) and one 6-point cone (having the worst as the lower generator and the others as upper generators). They report that using convex cones in sorting is effective and improves the output solution.

Recently, Dehnokhalaji *et al.* [11] propose an approach that uses convex cones and polyhedra to partially order a finite set of alternatives. Similar to the p cone efficiency concept discussed in Ref. [19], an alternative is classified as *surely better than*, *surely worse than*, or *possibly better/possibly worse than* the lower generator of the cone. This makes the suggested approach flexible in the sense that it can be used as an exact or approximate approach by adjusting some parameters. They generalize the idea used in Ref. [19] and employ it to obtain a strict partial order. This approach is suggested to be used to partially rank alternatives or as a supplementary method in other solution approaches such as evolutionary multiobjective optimization as discussed in Ref. [30]. Developing an interactive solution algorithm based on the approach is pointed out as a subject of future research.

Karsu *et al.* [31] use convex cones for solving MCDM problems involving equity concerns, which are encountered especially in public sector. They extend the current theoretical framework for convex cones by introducing the impartiality property to the preferences. On the basis of their theoretical findings, they propose an interactive ranking algorithm.

CONCLUSION

In this article, we consider the use of convex cones in interactive MCDM approaches, which is based on the DM's holistic assessments. We describe the assumptions on the DM's preference relation and the value function that allow us to implement the convex cones approach in solution algorithms for MCDM problems. We summarize the basic theoretical results from the literature, which show that convex cones can be used to iteratively approach the most preferred solution(s) by eliminating the ones that are less preferred. The results also show that, in multicriteria evaluation problems, polyhedra can be used alongside the convex cones for sorting or obtaining a quasi-ordering of the alternatives.

We provide a review of the studies that implement the convex cones approach over the last three decades. A large body of literature exists that use the convex cones approach in various algorithms designed to solve both multicriteria evaluation and multicriteria design problems. There are also studies on how to select good candidate solutions (cone generators) to be asked to the DM. We mention below a few challenges regarding convex cones approach awaiting further research.

- Further research can be performed on using convex cones to solve more difficult problems, such as multiobjective combinatorial optimization (MOCO) problems.
- Asking too many or relatively difficult questions increases the cognitive burden on the DM and may make the decision support system less attractive. Therefore, one needs to choose the type of interaction with the DM carefully. Further research can be conducted on finding the best way to minimize the cognitive burden while ensuring an effective decision support. Different types of questions can be asked to the DM. These include making pairwise comparisons, determining the best (worst) alternative in a given subset, or ranking a small subset of alternatives.

Experimental studies that compare these different interaction modes and discuss their advantages and disadvantages in different problem settings can be performed.

- As the size and number of cones used in an algorithm increase, more alternatives are eliminated but the computational time may increase as well. By generating merely 2-point cones, one may not be utilizing the available information fully. To the best of our knowledge, it is not studied in detail how well this approach works compared to generating the *minimal set of cones* in terms of the information required from the DM throughout the procedure. In other words, it is still an open question how to determine the cone sizes that best balance the computational time with the amount of information required from the DM for different problem settings.
- Using the information provided by the polyhedra in ranking and sorting environments is also a promising area. More research on the use of polyhedra and convex cones for sorting and ranking purposes awaits further attention.

INTRODUCTION

Since Norway started exporting natural gas in 1977, it has become the sixth largest producer and the third largest exporter of natural gas in the world. More than 30 production facilities in the North Sea send natural gas to receiving terminals in four European countries, covering approximately 15% of the total consumption in the European Union [1].

Almost all of the Norwegian natural gas is transported to the customers using a network of pipelines in the North Sea. With a length of more than 7800 km, it is the largest offshore pipeline network in the world, see Fig. 1. To ensure optimal operation of this network, the system has to be analyzed as a whole, including both production and transportation. Detailed knowledge of network integration, operational flexibility, pipeline flow and inventory, gas processing, and compressor station operation is required to analyze the behavior of the network. Variations in gas quality at the different production facilities and varying quality requirements from the customers add to the complexity of the system.

The petroleum industry has been an early adopter of operations research-based applications [3]. The Norwegian Petroleum

Directorate, for example, uses operations research for investment planning for oil and gas fields in the North Sea [4]. Other long-term planning models include designing and planning offshore field infrastructure under complex fiscal rules [5], and planning the development of offshore gas fields explicitly considering the uncertainty in reserves [6]. The upstream natural gas value chain, including production, transportation, processing, storage, and markets, is considered by Ulstein *et al.* [7], simultaneously optimizing all upstream activities on a tactical level. Pressure constraints in the transportation network, however, are not considered. Selot *et al.* [8] present an operational model for producing and routing natural gas. This model includes both a detailed description of the infrastructure and a complex contractual model for the markets.

The GassOpt model has been developed to help both natural gas producers and transportation network operators in planning their activities and maximize the value of their operations [9,10]. Given the production at the upstream facilities and the demand at the exit terminals, GassOpt determines the optimal routing, processing, and blending of natural gas ensuring that demand and quality constraints are satisfied. The development of the GassOpt decision support tool is described in more detail by Rømo *et al.* [9].

THE GASSOPT MODEL

The objective of the GassOpt model is to maximize the total flow of natural gas from the North Sea to the customers. In order to represent the real-world gas transportation problem correctly, the following elements have to be considered in the model formulation and are described hereafter: gas pressure and pipeline capacity, system effects, compressor stations, gas quality, and processing plants. Rømo *et al.* [9] and Tomasgard *et al.* [10] provide more details on how to model these elements.

Figure 1. Natural gas production and transportation network [2].

Gas Pressure and Pipeline Capacity

The flow capacity of a pipeline depends not only on its physical properties but also on the pressure difference between inlet and outlet. Offshore gas pipelines are typically very long with high inlet pressure, large pressure drop,

and contracted pressure obligations at the pipeline outlet, making it crucial to describe the relation between gas flow q and pressure difference (between inlet pressure, p_i , and outlet pressure, p_o) correctly.

For long pipelines, this relation can be described by means of the nonlinear

Weymouth, Panhandle A, or Panhandle B equations. These equations are derived from the fundamental energy equation for compressible flow and developed for turbulent high pressure flow in long pipelines. The flow capacity of a pipeline can be calculated depending on the physical pipeline properties (such as length (L), diameter (D), friction (E), and ambient temperature (T)) and gas properties (such as the compressibility (Z)), as well as set of constants (c, n, u, x, y), which differ according to which of the equations (i.e., Weymouth, Panhandle A, or Panhandle B) is considered. For standard conditions (temperature $T_{\text{std}} = 288.15$ K and pressure $p_{\text{std}} = 1.01325$ bar), the flow rate q_{std} is given as [11]

$$q_{\text{std}} = cED^n \left[\frac{T_{\text{std}}}{p_{\text{std}}} \right]^u \left[\frac{p_i^2 - p_o^2}{G^x L T Z} \right]^y.$$

The equation above can be simplified as we can compute a constant, C , for the physical properties of a given pipeline and its surroundings. The flow rate q through the pipeline is then given as

$$q = C (p_i^2 - p_o^2)^y.$$

System Effects

For a single pipeline, the link between pressure and capacity is easy to handle. In large gas transportation systems with interconnected pipelines and processing plants, however, changes in pipeline pressure or composition of the gas flow in one part of the transportation network can affect the gas flow or the capacities in the remaining network as well. It is therefore insufficient to analyze only a part of the network. To assess the system effects, the gas production and transportation network has to be analyzed as a whole.

Compressor Stations

It is important to include pipeline pressure as a variable in the model. The ability to raise pipeline pressure results in a more realistic utilization of pipeline capacity. The total energy consumption of the compressor stations is then included in the objective

function, giving a better representation of both the real-world operations of the network and the operating costs.

The power W consumed by the compressor in order to raise pipeline pressure depends on the following variables: the flow q through the compressor, as well as inlet and outlet pressure, p_i and p_o . Thermodynamic properties of the natural gas such as its inlet temperature (T_i) and its compressibility factor (Z_i) affect the necessary compressor power as well. Compressor-specific operational characteristics for flow Q , inlet and outlet pressure, P_i and P_o , compressor efficiency (η), as well as the standard conditions (temperature $T_{\text{std}} = 288.15$ K and pressure $p_{\text{std}} = 1.01325$ bar) also have an impact on the power consumption. The nonlinear relationship between power, flow, and pressure can be linearized and approximated by the following formula [12]:

$$W = \left(\frac{P_i Q}{\left(\frac{2}{3}P_i + \frac{1}{3}P_o\right)^2 P_o} - \frac{P_o Q}{\left(\frac{2}{3}P_i + \frac{1}{3}P_o\right)^2 P_i} + \frac{P_o - P_i}{\frac{2}{3}P_i + \frac{1}{3}P_o} q \right) \cdot \frac{p_{\text{std}} Z_i T_i}{\eta T_{\text{std}} \times 24 \times 3600}.$$

Gas Quality

The quality of natural gas is described by means of its energy content. This energy content is expressed in terms of gross calorific value (GCV) or Wobbe index (WI). The WI represents the relationship between GCV and the relative density (specific gravity) of the gas. Customers make their nominations in energy content, and gas sellers must deliver gas with GCV and WI values within maximum limits.

Natural gas is a mixture of different components. Its composition and thus its energy content depend strictly on the production facility considered. Blending gas from different fields allows for a better utilization of the available resources to satisfy customer demand. This is challenging to model, as we have to keep track of the quality in every node and pipeline, especially when blending and splitting gas flows. Modeling natural gas using multiple components and considering

gas qualities introduces a so-called pooling problem [13,14] that increases the complexity of solving the mathematical model considerably.

Processing Plants

Processing plants usually remove contaminants (such as CO_2 or H_2S), heavy hydrocarbons, sour gases, and water. Some of these components have a market value and can be stored in storage tanks and are sold in a downstream market. Another important reason for modeling CO_2 removal in processing plants is to avoid corrosion problems in pipelines caused by high CO_2 content.

In addition to restrictions on the GCV and WI, customer requirements limit the allowed amount of contaminants at the exit terminals. Detailed modeling of processing plants can reduce the risk for off-spec deliveries and increase the total value of natural gas deliveries.

MODEL IMPLEMENTATION AND SOLUTION

The basic structure of the GassOpt model is a network flow model. However, modeling the different elements of the natural gas production and transportation system results in a nonlinear problem, not suited for most commercial solvers. In particular, the relationship between gas pressure and pipeline capacity as well as the pooling constraints due to gas quality requirements introduce nonlinear constraints to the model.

The GassOpt model uses the Weymouth equation to determine pipeline capacity. This equation can be linearized by means of a Taylor series expansion. In order to deal with the pooling constraints, the formulation for splitting gas flows is discretized. We introduce a set of binary variables in each split node for modeling the split fraction. See Tomasgard *et al.* [10] for a more detailed description and mathematical formulation.

In general, there will be several possible strategies for fulfilling the customer nominations. In order to have the model generate realistic flows and pressure values in the system, several penalty terms are added to

the objective function. These penalty terms apply to the total system pressure level and to deviations from the preferred flow split in certain nodes. In addition, deviations from contracted gas deliveries to customers in terms of volume are penalized in the objective function. Deviations with respect to minimum delivery pressure and gas quality limits are not allowed. Tests show that these terms do not significantly reduce the maximum flow potential but cause the model to choose more realistic flow patterns and pressure levels.

The model is implemented in Mosel and solved using XpressMP. Most of the real-world problem instances can be solved with an optimality gap of 0.5% within 20 min. There are, however, a few problem instances for which the optimality gap still exceeds 5% after reaching the runtime limit. The optimality gap seems small, but, given the market value of natural gas, this gap may represent several million USD in lost revenues.

USERS OF GASSOPT

The GassOpt model is developed in close cooperation with Statoil and Gassco. Statoil is Europe's second largest supplier of natural gas and the sixth largest in the world [1], whereas Gassco operates the transportation network on the Norwegian Continental Shelf. Both companies use the model in their planning processes, though the main focus of the analysis is different.

Statoil uses the GassOpt model in their long-term planning, evaluating the operational consequences and different investment decisions by considering all production facilities as part of the same production portfolio. In case of disruptions in production or transportation, the model is able to determine how to satisfy the customers' demand by rerouting the gas or moving production volumes from one facility to another.

Gassco administers access to the pipeline network. All producers on the Norwegian Continental Shelf have to book transportation capacity with Gassco. The GassOpt

model allows Gassco to quickly check the feasibility of the transportation bookings with respect to quality and capacity constraints. Gassco is also responsible for further developing the upstream network. Using the model enables Gassco to identify bottlenecks and propose necessary investments for increasing the network capacity and avoiding off-spec deliveries. The effect of changes in the infrastructure regarding contracted gas quality, required pressure levels, and capacities can be easily evaluated.

BENEFITS

One way of measuring the benefits of using GassOpt is, of course, calculating the monetary effect of using the model. Because of GassOpt's system perspective, Statoil can reallocate production and reroute gas to better meet customer specifications. The company estimates the accumulated savings due to an increase in fulfillments of contractual obligations at around USD 150–300 million.

GassOpt is also used to analyze the consequences of investments in infrastructure. Owing to the improved decision support that GassOpt provides to the decision makers, investments can be better targeted at removing bottlenecks in the network, ensuring that the capacity of the network meets the producers' requirements. The savings from avoiding bad investment decisions are conservatively estimated at around USD 900 million so far.

Another important factor, often observed with the use of optimization methods [15], is an improved understanding of the system's complexity. By understanding the technical aspects of the network and formulating them as a mathematical model, both researchers and practitioners increase their knowledge over the impact of decisions on the operations of the system.

FUTURE DEVELOPMENTS

Owing to the increased amount of contaminants present in recently developed gas fields, gas quality is becoming more important.

Blending and splitting of natural gas from different fields will be necessary to a greater extent, not only to meet the contractual obligations in the markets but also to fulfill the quality specifications of the processing plants. Future research will therefore focus on a system-wide quality management, extending the quality requirements upstream to ensure optimal operation of the processing plants as well. The blending and splitting processes introduce pooling constraints, such that future efforts will also be directed toward solving the resulting mathematical model.

Another possible improvement is to make the model more dynamic. As of today, the model only allows for a steady-state analysis of the production and transportation network, but cannot capture changes within the planning period. Modifying the model for a multiperiod setting will also facilitate modeling linepack and introduce additional flexibility for the operations of the network.

INTRODUCTION

In the United States Presidential election in 2000, candidates George W. Bush and Al Gore were locked in an extremely tight contest. Because of how the United States elects its President through the Electoral College, the contest depended on the outcome of the state of Florida; whichever candidate won the popular vote in Florida would be named the next President of the United States. Election Day on November 7, 2000 ended with no clear winner in the popular vote in Florida because the results were too close to call and many ballots had to be recounted. This set off a chain of events that culminated in the US Supreme Court case of Bush versus Gore and the eventual outcome that George W. Bush was determined to have won the Florida popular vote by a margin of 537 votes; hence Bush became the 43rd President of the United States.

Much of the controversy in Florida in 2000 centered on having to interpret votes made using punch-card ballots. Punch-card ballots allow the voter to punch out a small piece of perforated paper (typically known as a *chad*) next to the candidate's name or the ballot issue for which the voter wishes to cast her ballot. Difficulties were encountered by election officials when trying to decide the intention of voters who cast ballots that had only

partially punched out the chad or punched multiple chads for candidates for the same office; these became known as *dimpled chads*, *pregnant chads*, and so on. Matters were further complicated when some observers felt that the punch-card ballots used in Florida had been poorly designed and could have led to voters casting their vote for the wrong candidate. Other issues that may have affected the outcome of the election in Florida in 2000 included the media initially predicting that Gore would win the state before all election polls had closed [1]. It is impossible to determine the exact effect these combined events had on the election in Florida, but it was clear to election administrators that changes needed to be made in the administration of future elections.

In order to prevent a repeat of the difficulties encountered in the 2000 election, Congress passed the Help America Vote Act (HAVA) in 2002. HAVA sought "to establish a program to provide funds to states to replace punch card voting systems" [2]. Congress provided funds for these upgrades, but the decision of which exact new method to choose was left to the local election boards. Because part of the HAVA requirements for the new voting systems was that voters should be able to verify and change ballot errors, the new voting technologies were overwhelmingly of two basic types: optical-scan machines and direct-recording electronic (DRE) machines (Figs 1 and 2).

Each of these new systems (optical-scan and DRE) presented new operational challenges in voting that had to be overcome. Optical-scan machines are bulky, heavy items that are typically delivered by truck; this creates a difficult-to-solve instance of a vehicle-routing problem that administrators must solve to get the machines to the polling locations on time. DRE machines are expensive; thus, they are a scarce resource. Because DRE machines are the bottleneck in the voting process, improper allocations of DRE machines to polling locations can create queues to vote and excessive waiting

Figure 1. Example of a direct-recording electronic (DRE) voting machine (also known as a *touch-screen voting machine*).

times for voters. Interestingly, these challenges are somewhat specific to the type of voting technology being used. Unlike DRE machines, optical-scan machines are not typically the bottleneck in the voting process, so it is generally sufficient to have one optical-scan machine per precinct. Because DRE machines are typically much smaller than optical-scan machines (about the size of a laptop computer), they can usually be delivered to polls by poll workers in their personal vehicles.

Because of the widespread impact of elections and the importance of providing fair and efficient voting systems, voting presents unique opportunities for OR to improve social welfare. Previous work in OR has focused on predicting election results (e.g., Refs 3 and 4) which extends the extensive work on forecasting election results in political science and other fields ([5] for an overview of election forecasting applied to US presidential

Figure 2. Example of an optical-scan voting machine.

elections and [6] for an overview of models applied to elections in countries outside the United States). Bozkaya *et al.* [7,8] and King *et al.* [9] demonstrate the use of OR methods to problems related to political districting where geographical boundaries are defined to separate different political districts to accomplish some specific objective (balancing political representation, number of voters per district, etc.). More similar to the work presented in this article, other researchers have examined the use of OR methods to improve the efficiency and equity of voting systems. Fry and Ohlmann [10] investigate the problem of how to deliver optical-scan voting machines to precincts; Refs 11–17 specifically consider the problem of how to allocate voting machines to precincts. In this article, we examine more closely the problems and solution techniques presented in Refs 10,16,17.

CHALLENGES PRESENTED BY OPTICAL-SCAN VOTING MACHINES

Optical-scan voting machines are similar to scantron-based technology used in many

educational institutions to grade multiple-choice exams. The voter fills in a box or circle next to each candidate or issue choice for which she wishes to cast her ballot. Once the voter has completed voting, the ballot is scanned by the optical-scan voting machine to ensure that the voter has not cast any disallowed votes (e.g., voting for too many candidates for the same office). If the ballot is found to be in error, the voter can correct his/her ballot.

The operational challenge presented by these types of voting machines is that they are large and heavy, to the extent that they typically must be delivered to the polling location by a large moving truck because they do not fit in most passenger-sized cars. This creates a significant change in many localities that had previously used punch-card ballots, which require only a stack of punch cards and usually a collapsible ballot box. The punch cards and ballot box were very small, so they could be picked up by a poll worker on the morning of the election and delivered to the polling location. However, with optical-scan machines, the voting machines would have to be delivered to the polling location by a specialized delivery truck. These deliveries often had to be made days in advance of the election, in which case someone would have to be available to receive the machine and then, as mandated by law, it would have to be kept in a secured area until Election Day.

In order to accommodate the schedules of those receiving the machines, many election boards solicited delivery times when someone would be available to receive the voting machines at each polling location. Thus, the delivery requirements necessitated by the use of optical-scan voting machines created a classic version of the vehicle-routing problem with time windows (VRPTW). In even moderate-sized localities, the number of delivery locations and number of voting machines to be delivered creates a challenging problem to solve. Consider the case of Hamilton County, Ohio, which in 2006 had 966 optical-scan voting machines to deliver to 531 different polling locations. Each of these 531 different polling locations submitted time windows when they could receive the voting machines, which created a problem that was

intractable to most easily implemented solution approaches.

The VRPTW is a well-studied problem in OR; many exact and heuristic solution approaches have been examined. In order to keep solution times fast even for large problems and to prevent boards of elections from having to purchase dedicated optimization software, heuristic solution approaches are generally preferred in this setting. Fry and Ohlmann [10] present a penalty-based annealing heuristic to solve this problem. The authors' approach augments traditional simulated annealing by relaxing both time windows and capacity constraints via variable penalty terms. The objective in the authors' models is to minimize the travel distance for a fixed number of vehicles. The authors iteratively increase the number of vehicles available and resolve the problem to determine both the number of vehicles required and the total travel distance.

Fry and Ohlmann [10] report that they used this solution approach to design delivery routes for Hamilton County for several election cycles. The authors provided turn-by-turn directions to the delivery drivers who found that they were able to deliver almost all voting machines during their prescribed time window. The authors also found that they could generate much "better" solutions (in terms of requiring fewer vehicles and fewer miles traveled) by slightly modifying the time-window selection method for the delivery locations. Instead of allowing each location to choose an unconstrained time window, delivery recipients could be asked to select a set of days when delivery could be accepted as well as whether the delivery could take place in the morning, afternoon, or anytime during the day. The authors found that the responses to these solicitations gave much wider time windows than simply asking the recipient to state an available time window for delivery. Soliciting multiple possibilities for the day of delivery necessitates a two-phase solution method where first each polling location must be assigned to a delivery day and then the resulting collection of VRPTW instances must be solved using the authors' penalty-based annealing approach.

The two phases can then be solved iteratively to improve the overall solution. Fry and Ohlmann [10] claim that allowing multiple delivery days greatly reduces the required number of vehicles and required miles traveled. This new method for soliciting delivery time windows was instituted for several of the later years in which the authors performed this service for Hamilton County with great success.

CHALLENGES PRESENTED BY DIRECT-RECORDING ELECTRONIC (DRE) VOTING MACHINES

Many counties that do not use optical-scan voting machines in the United States use DRE voting machines, also known as *touch-screen machines*. Voters cast their ballots on DRE machines by touching the screen to indicate their voting preferences; DRE machines do not require any paper ballots (although many now also provide a paper record for auditing purposes). The advantage of DRE machines is that ballots can be easily modified to accommodate voters with disabilities and voters who require ballots in languages other than English. DRE machines are also much smaller and lighter than most optical-scan machines, easing the logistical burden of getting the machines to the polling locations. However, DRE machines are quite expensive which means that boards of elections must be judicious in their allocation of machines to precincts. In addition, DRE machines often require that the voter scroll through several pages of text to complete their ballot (recent ballots in Ohio have required voters to make decisions in 20 or more political offices and 9 or more ballot initiatives). Traditional voting systems often permitted voters to see all races and issues simultaneously and easily skip over items not of interest. Thus, DRE machines generally require more time for each voter to cast her ballot. An important decision for election boards is then the need to allocate the limited number of voting machines to precincts to promote efficiency and equity in the voting process.

Many voters in recent elections have suffered from inefficient and allegedly unfair

allocation policies. For instance, in the 2008 presidential election, some precincts in Franklin County, Ohio, recorded wait times greater than 5 h for many voters. Excessive wait times have also been reported in elections outside the United States; Adam [18] reports on long lines at the polls in the United Kingdom in 2010. Because it is estimated that 2–3% of voters are lost for every additional hour of wait time at the polls [13], such extended wait times can lead directly to voter disenfranchisement. However, simply minimizing some aggregate measure of voter wait times is not sufficient in this context; it is also important to ensure that voters are treated equitably across polling locations. Voters' geographic location is often strongly correlated with their political preferences [19]. Thus, if some precincts experience longer wait times than others, then this could give advantage to one political party over another or one particular outcome of a ballot initiative. This problem is exacerbated by the fact that ballot lengths often differ by precinct; hence, if voter service times are not considered in allocation decisions, then elementary queueing theory suggests that some precincts will experience longer waiting times. As an illustrative example, political science professor Walter Mebane found that African Americans waited on average 30 min longer to vote than other voters in Ohio in 2004 [20]. In a close election, such a result could clearly impact the outcome.

Voting systems should embody efficiency and equity. "Efficiency" refers to minimizing some aggregate measure of voter waiting times; and "equity" refers to having approximately equal waiting times for voters among the various precincts. The most commonly used allocation method in practice is to assign voting machines proportional to the number of registered voters in a precinct; this method is usually referred to as *proportional allocation*. However, waiting times are a function of both arrival rates and service times. Service times are affected by ballot lengths and differences in voter demographics, both of which can vary from precinct to precinct. Proportional allocation ignores differences in service times as well as any nonstationary arrival patterns of voters on Election Day.

Perhaps even more important, due to the highly charged political nature of election administration, decisions regarding voting machine allocations should be unbiased and transparent. The use of OR-based allocation methods promotes transparency and prevents bias.

On Election Day, a random number of voters arrive at each precinct throughout the day. Voters wait in line until a voting machine is available. This is an example of a parallel queueing system where the voters are the “customers” and voting machines are “servers.” The stochastic nature of both customer (voter) arrivals and service (voting) times, combined with limited server resources, results in voter queues and the potential for excessive waits.

The voting process captures many classical elements of a queueing system. Voter arrivals are random; in fact, even the total number of voters to arrive at a location is extremely unpredictable and is influenced by the nature of the election, general voter sentiment, and even the weather. The time required to cast a ballot is also uncertain, and it is highly affected by the length of the ballot, which can vary across polling locations. In most cases, voters form a single queue to use the next available voting machine. For DRE-equipped locations, the DRE machine is the bottleneck. The DRE machine is in use for the entire time that a voter is completing his or her ballot. In such cases, the DRE machines act as servers and voters as customers in a traditional $G/G/s$ -queueing system. However, there are additional complications that prevent classical queueing models from applying exactly. Voter arrivals are often nonstationary owing to voter work schedules and busy periods [12]. The short length of Election Day, usually less than 14 h, often prevents steady-state analysis and may even allow for time periods where utilizations exceed 1. Thus, traditional queueing models may be a questionable approximation of the reality of Election Day.

Determining an optimal voting-machine allocation is challenging for several reasons. (i) The arrival process is constrained in that no more voters can arrive than the number registered, a violation of the standard

queueing assumption of an infinite calling population. There are often surges in voter arrivals, contrary to the typical queueing assumption of stationary arrival processes [12]. Moreover, it is difficult to forecast turnout rates due to many uncontrollable variables (e.g., weather). (ii) Voting systems may violate traditional steady-state queueing-theory assumptions. For example, in the 2004 elections in Franklin County, Ohio, several precincts experienced average arrival rates that were higher than their average service rates, which would imply queue “explosion” in conventional queueing theory. Ohio law requires that the polls be open 13 h, plus however much time is needed to accommodate voters waiting when the polls close to new arrivals. (iii) Actual voting scenarios involve considerable computational complexity. A metropolitan area can consist of over 500 precincts and over 4500 voting machines to be allocated. The result is either a large-scale nonlinear stochastic optimization problem using traditional analytical queueing approximations that may not be valid, or a complicated simulation model. Thus, both model building and developing solution methods are challenging.

The literature directly examining voting-system operations includes Refs 11–15. Floyd [11], Edelstein [12], and Allen *et al.* [14] use simulation to model waiting times, allowing consideration of the realistic complications in their models, such as equipment failures and nonstationary arrivals. However, none of these papers explicitly considers voter equity. Allen and Bernshteyn [13] suggest simple analytical queueing models to predict average voter waiting times for given machine-allocation policies, and suggest an optimization model to allocate voting machines; they do not consider complicating issues such as nonstationary arrivals, machine failures, or specific differences in voting-time requirements due to differences in ballot lengths. Yang *et al.* [15] develop a simple heuristic to allocate voting machines based on simulation models, but they assume that voting-time distributions are identical across all precincts, and they do not provide optimality guarantees for their solutions.

In order to achieve the dual objectives of efficiency and equity, Yang *et al.* [16] build a large-scale resource-allocation model that can be solved very efficiently using heuristic methods with provable bounds for solution quality. The authors choose the maximum difference among waiting times as the inequity metric of interest, which allows for waiting times other than means (e.g., order statistics). The authors develop a two-phase algorithm utilizing simulation-optimization techniques to allocate resources equitably in a stochastic environment. To accommodate nonstationary arrivals of voters, the authors use simulation to estimate voter waiting times that allow for nonstationary arrivals, machine failures, and so on.

The authors illustrate the effectiveness of their algorithm by applying it to the allocation of voting machines in 2008 in Franklin County, Ohio, to minimize the inequity of voter waiting times among precincts. In 2008, election administrators in Franklin County were responsible for allocating 4625 DRE voting machines to 532 precincts. Table 1 [16] compares the authors' suggested allocation to the actual allocation used in 2008 based on the range of the 90th-percentile-order statistics of the waiting time distribution ($Z(X)$), the maximum waiting times experienced at a precinct ($Z_1(X)$), the system-wide expected waiting time ($Z_2(X)$), and the probability of wait times exceeding 30 min ($Z_3(X)$). The results in Table 1 show that implementing the authors' allocation during the 2008 election would have shortened voters' average wait times by 36% and resulted in 23,000 fewer voters waiting for more than 30 min—preventing voters from balking and being effectively disenfranchised. The authors' algorithms not only provide the rigor and transparency required by high-profile, and often contentious,

national elections, but these algorithms can be applied in a spreadsheet environment making them accessible to public-service officials in practice.

In addition to better allocations of available DRE voting machines, other potential operational changes in voting systems can also reduce voter waiting times. Yang *et al.* [17] discuss operational improvements related to early voting, educating voters, and providing feedback about line length at polling locations. Early voting (often called *absentee voting*) is becoming increasingly popular in many states; 16 and 22% of voters chose early voting in the 2000 and 2004 Presidential elections respectively. Early voting serves to decrease the arrival rate of voters to the polls on Election Day, thereby reducing utilizations and decreasing wait times. Early implementations suggest that informing voters about when polling stations are less busy may encourage voters to avoid peak times. Boards of elections in the District of Columbia, Utah, and some counties in Florida posted real-time waiting time estimates for early voters on their Web sites during the 2010 election [21]. Such efforts smooth the arrivals of voters over Election Day and can again reduce voter wait times. Clearly, voting queues can also be reduced if the time required for a voter to cast a ballot decreases. Boards of elections can use their websites to educate voters to become familiar with the issues on ballots and new voting machines prior to voters' casting the ballots. They can also provide sample ballots and voting machine instructions at polling stations while voters are waiting in line. Simulation results suggest that such measures can be equivalent, in terms of reducing queues, to adding a significant number of voting machines to polling locations.

Table 1. Allocation Comparisons (min)

Allocation	90th-Percentile of Waiting Time, $Z(X)$	Maximum Waiting Time, $Z_1(X)$	System-Wide Expected Waiting Time, $Z_2(X)$	Probability of Long Wait, $Z_3(X)$
Yang <i>et al.</i> (2012)	13.91 ± 0.75	36.74 ± 0.647	5.87 ± 0.0033	0.0427 ± 0.00010
Actual	72.91 ± 1.05	90.11 ± 1.321	9.17 ± 0.0048	0.1250 ± 0.00011

Note: Intervals are based on 95% confidence levels.

Yang *et al.* [17] also examine the robustness of their allocation methods since, clearly, factors such as the number of arriving voters are not known with certainty prior to Election Day. The authors show that their OR-based allocation method is fairly robust compared with competing heuristics to uncertainty of arrival rates; their allocation algorithm is shown to reduce mean voter waiting times by an average of 71% compared to the proportional allocation method even when voter turnout rates are not known with certainty.

CONCLUSIONS AND FUTURE EXTENSIONS

A common challenge facing researchers in applying OR to voting operations is that the optimality of solutions depends on the accuracy of key input parameters such as voter turnout and service times at the precinct-by-precinct level, which has proven difficult to predict with desirable confidence before Election Day. More work needs to be done in developing models to better estimate voter turnout by demographics, ballot issues, weather, and so on. Meanwhile, researchers can explore robust optimization techniques to create voting machine allocations that are designed to be insensitive to imprecise parameter estimates.

Additionally, work should be done to explore policies for dynamically allocating voting machines during Election Day. Currently, allocation decisions must be made weeks to months in advance of Election Day. Once Election Day arrives, the actual arrival of voters to different polling locations can be significantly different than expected. Complicating matters, voting machines are subject to failures, which can also create long queues to vote. Thus, methods for reallocating voting machines among precincts during Election Day are important to promote efficient and equitable voting systems. Some boards of election have experimented with keeping machines in reserve to allocate on Election Day to reduce voting queues, but these approaches have not been formally evaluated, and the implementation in practice has been frustrated owing to poor planning and execution. OR would seem to

possess many models for developing and testing potential reallocation policies.

Election operations provide an exciting opportunity for OR to have significant impact on an issue with clear social-welfare implications. The authors of Refs 16 and 17 participated in drafting House Bill #260, which was passed in the Ohio State House of Representatives and is pending in the Ohio Senate. The bill mandates that voting-machine-allocation decisions in Ohio should consider queueing effects in terms of expected voter arrivals and expected service times of voters. Passage of Ohio House Bill #260 marks a substantial achievement for applying OR methods to voting operations. It is hoped that this work and related endeavors will encourage more expanded use of OR in public-policy decisions.

USING QUEUEING THEORY TO ALLEVIATE EMERGENCY DEPARTMENT OVERCROWDING

LINDA V. GREEN
Armand G. Erpf Professor,
Columbia Business School,
New York, New York

THE GROWING PROBLEM OF ED OVERCROWDING

Timely access to care is a key component of high quality health care. Yet, patient delays are prevalent throughout the health-care system resulting in dissatisfaction and adverse clinical consequences for patients as well as potentially higher costs and wasted capacity for providers. For this reason, the Institute of Medicine has identified “timeliness” as one of the six keys in “aims for improvement” in its health-care quality initiative.

Arguably, the most critical delays for health care are the ones associated with health-care emergencies. Unfortunately, emergency department (ED) overcrowding is a continuing and growing problem. In a 2007 survey [1], nearly half of all US hospitals and 65% of urban hospitals reported being at or over capacity in their emergency rooms, resulting in long waits before being seen by a physician and delays of many hours or even days in getting a hospital bed. Each of these sources of delay can be life-threatening.

Delays for ED Physicians

Delays for emergency care generally begin with the wait to be seen by a physician. Upon arriving to the ED, patients are generally triaged into three major categories reflecting the severity and time-sensitivity of their condition. The most serious category is “emergent” (requiring “immediate” care), followed by “urgent” (requiring care within a “short” period of time) and “non-urgent.”

Though many patients are non-urgent and would not be harmed by significant delays in seeing a physician, many, if not most, are either “emergent” or “urgent.” However, recent studies have revealed that waits to see an ED physician are long and getting worse. In the United States, the overall median wait to see an ED physician increased from 22 min in 1997 to 30 min by 2004. More alarmingly, the median wait for patients diagnosed with acute myocardial infarction (AMI), who are emergent, increased from 8 min in 1997 to 14 min in 2004 [2]. These figures are considerably higher in urban areas and for teaching hospitals where most emergency care is delivered. Given the urgency of rapid treatment for victims of heart attack (as well as for sepsis, stroke, pneumonia, and trauma, among others) these figures, as well as anecdotal reports of patient deaths in EDs, indicate that these delays are a serious threat to the health and well-being of all those who need emergency care.

In addition, previous studies have established a strong link between long emergency department delays and the fraction of patients who leave without being seen (LWBS) [3,4]. The proportion of LWBS is itself an important measure of emergency department performance and quality of care. Several studies have concluded that patients who LWBS are sick and most require emergency care. One study has shown that up to 11% of patients who LWBS are hospitalized within a week and 46% of patients were judged to require immediate medical attention [5].

Delays for Inpatient Beds

Though insufficient ED physician levels are responsible for significant and serious delays in emergency care, the single biggest cause of ED overcrowding is the lack of inpatient beds [1]. About 25% of ED patients are admitted to the hospital and roughly 40% of inpatients come through the ED. For US hospitals reporting ED capacity problems, the average

time to move a patient from the ED to an inpatient bed once the decision to admit has been made is over 4.5 h and bed delays of over 24 h are not uncommon [6]. These delays lead to large numbers of patients “boarded” in the ED who strain the ability of the physicians and nurses to care for them. This ED overcrowding also compromises the ability of ED physicians to treat new arrivals to the ED.

When this kind of situation becomes untenable, a hospital will usually go on ambulance diversion—suspending new ambulance arrivals to the ED. In a 2007 survey, over half of all urban and teaching hospitals in the United States reported being on diversion in the past 12 months [1]. When hospitals are on diversion, seriously ill patients have to travel further to get to the nearest hospital increasing their risk for adverse outcomes. In addition, due to the increased travel time, waits for ambulances increase, further endangering patients. A recent study based on data from New York City showed that when there are significant levels of ambulance diversion in a borough, the number of deaths due to AMI increases by 44% [7].

Bed delays can occur even when inpatient beds are available. This is because patients and beds are not all identical. Hospitals are divided into nursing units which typically consist of between 20 and 50 beds. Each nursing unit is used for one or more clinical services (i.e., medical, surgical, pediatric, obstetrics, cardiology, neurology). So a patient with heart disease who is waiting in the ED for a bed may experience a significant delay if all the cardiology beds are occupied even though beds may be available in other clinical units. In addition, some patients need telemetry beds, which, in many hospitals, are not available in all nursing units. Finally, most hospital rooms have two or more beds which can be used only by patients of the same gender. So it is possible, for example, for a female patient to be delayed in getting an inpatient bed if the only beds that are available are in rooms occupied by male patients.

The most common delays for inpatient beds are for critical care beds [1]. Intensive care units (ICUs) are usually the most

expensive units in the hospital due to both the technology utilized and the high level of staffing needed. The full per-day cost in an ICU is about three to five times as much as in a regular inpatient unit [8] and therefore, hospital administrators believe that these beds should be highly utilized in order to be “cost-efficient.” Consequently, delays are often the longest for these beds which are used for the most seriously ill and injured patients.

Delays Due to Unavailability of Nurses

Nursing costs comprise a substantial fraction of hospital budgets and therefore cost-effective nurse staffing is very important. In most hospitals, the number of nurses assigned to a unit is determined by a specified ratio of patients to nurses. The historical norm for most types of clinical units has been 8:1, while for intensive care units it could be as little as 1:1. Though most hospitals subscribe to these standards, cost pressures and a national nursing shortage have resulted in these ratios being exceeded in many cases. Sometimes, however, this is the result of a failure to adequately plan for the daily, weekly, and sometimes seasonal variations in hospital census that are common in most clinical units of virtually every hospital.

Insufficient inpatient nursing levels are associated with patient dissatisfaction as well as increased levels of medical errors [9,10]. However, nurse unavailability is also a major factor in delays for beds in the ED. In order for a patient to be transferred to an inpatient bed from the ED, a nurse needs to be available to handle the admission to the unit. So, if the staffing level in the unit is such that the nurses are highly utilized, patients waiting for a bed in that unit will continue to wait even when a bed becomes available.

Nursing levels also play a role in delays for care within the ED. As in other parts of the hospital, nurses are the primary managers and caretakers of patients. If the number of patients in the ED becomes too high for the nurses to handle, new arrivals may not be taken into the treatment area until some of the current patients are discharged or moved

to inpatient beds. If the ED is very congested, the hospital may go on ambulance diversion.

Delays due to lack of nursing personnel may be more prevalent in the ED than in other parts of the hospital. The variability in the volume and pattern of patient arrivals, as well as the diversity of medical problems in the ED, make it a difficult environment for which to predict nursing needs. And the stress of the work environment in the ED makes it harder to attract and retain nurses and often results in high levels of absenteeism. Since the need for rapid treatment is generally greater in the ED, these delays may be particularly problematic.

USING QUEUEING THEORY TO REDUCE DELAYS FOR EMERGENCY CARE

Delays for ED Physicians

As mentioned above, visits to EDs have been steadily increasing. Constrained provider capacity relative to demand volume is exacerbated by the extreme variability in demand during each 24-h period experienced by a typical emergency department. This time-of-day pattern, as reported in the National Hospital Ambulatory Medical Care Survey for 2002, is distinguished by a relatively low level of demand during the night followed by a precipitous increase starting at about 8 or 9 a.m., a peak at about noon, and persistently high levels until late evening [6]. In addition, though the general pattern of demand is similar across the days of the week, individual days are likely to experience different overall volumes as well as slight differences in the exact timing of peaks and valleys. In particular, emergency departments are likely to have fewer visits on weekends than on weekdays.

Though physician staffing levels are generally varied over the day to meet these changing levels, this is usually done without the aid of operations research (OR) models. In a study conducted in the ED of a mid-size urban hospital in New York City [11], the overall average volume varied from a low of 63 patients per day on Saturdays to a high of 72 patients per day on Mondays. This degree of variation indicated that the then-current

policy of identical staffing levels for all days of the week was likely suboptimal. However, it was deemed impractical to have a different provider schedule every day and so it was decided to use queueing analyses (see section titled “Delays for Inpatient Beds”) to develop two schedules: weekday and weekend. This required aggregating ED arrival data into these two groups. For each, demand data were collected for each hour of the day using the hospital’s admissions database to understand the degree of variation over the day to explore the impact of different shift starting times and/or staffing levels on delays.

Estimating the average provider service time per patient was difficult. This time includes several activities including direct patient care, review of X-rays and lab tests, phone calls, charting, and speaking with other providers or consultants. In many, if not most, hospitals, these data are not routinely collected. At the time of the study, provider service times were not recorded and were estimated indirectly from direct observation and historical productivity data. Discussions with ED physicians revealed that the time spent on a patient was not necessarily linked to patient triage status and so it was decided to use a single estimate for the average time per patient.

Traditionally, in a service system with time-varying arrivals, the desired staffing levels would be determined by the *stationary independent period by period* (SIPP) approach which begins by dividing the workday into planning periods, such as shifts, hours, half-hours, or quarter-hours. Then a series of stationary queueing models, most often $M/M/s$ type models (see *The M/M/s Queue*), are constructed, one for each planning period. Each of these period-specific models is independently solved for the minimum number of servers needed to meet the service target in that period. In Ref. 12, the SIPP approach was shown in many cases to seriously underestimate the number of servers needed to meet a given delay performance target. This is particularly true when the mean service times are high (e.g., 30 min or more) and planning periods are long (two hours or more). In these situations, it was demonstrated that a simple variant of

SIPP, called Lag SIPP, performs far better than the simple SIPP approach. The major reason is that in cyclical demand systems, there is a time lag between the peak in the arrival rate and the peak in system congestion. This lag is significant when the mean service time is long. Lag SIPP corrects for this factor.

In our ED physician staffing study, the Lag SIPP approach was applied by first advancing the arrival rate curve by our estimate of the average physician time per patient, 30 min. A series of $M/M/s$ models were then constructed for each 2-h staffing interval, using the average arrival rate for each based on the time-advanced curve and the estimated average 30-min service time. Linear regressions for arrivals for the 2002 calendar year showed that the ratio of the mean to the variance of the number of emergency department patient arrivals each half-hour by day of week was consistently close to one yielding strong support for the assumption of time-varying Poisson arrivals. Since there was no data on provider times and estimates were only available for the mean, the assumption of exponential service times seemed most appropriate. The delay standard we choose was that not more than 20% of patients wait more than one hour before being seen by a provider. The use of one hour is consistent with the time standards associated with emergent and urgent patient groups used in the National Hospital Ambulatory Medical Care Survey [6]. The 20% criterion reflected the approximate percentage of non-urgent arrivals at the study institution.

The modeling results gave the number of ED physicians needed in each of the 2-h staffing intervals to meet the delay standard. In total, 58 physician hours were needed on weekdays to achieve the desired service standard, which represented an increase of 3 h over the existing staffing level of 55 h. Model runs for the weekend indicated that the target performance standard could be achieved with a total of 53 provider hours. In both these cases, the queueing analyses suggested that some physician hours should be switched from the middle of the night to much earlier in the day. A more subtle change

suggested by the model was that the increase in staffing level to handle the morning surge in demand needed to occur earlier than in the original schedule. Though resource limitations and physician availability prevented the staffing suggested by the queueing analyses from being implemented exactly, the insights gained from these analyses were used to develop new provider schedules. More specifically, as a result of the analyses one physician was moved from the overnight shift to an afternoon shift, 4 h were moved from the weekends and added to the Monday and Tuesday afternoon shifts (since these were the two busiest days of the week) and a shift that previously started at noon was moved to 10 a.m.

At the time of the study, the study hospital did not collect data on delays to be seen by a physician. So the impact of the new staffing levels was evaluated by focusing on the effect on the percentage of LWBS. Two 39 week periods—one before the staffing changes (August 26th, 2002–May 25th, 2003) and one after the staffing changes (September 1st 2003–May 30th 2004)—were studied. Matching weeks were chosen to better control for seasonal variation in both volume and disease states. The intervals are not aligned by exact date as to control for number of total days as well as days of the week. Despite an increase in patient arrival volume of 6.3%, an increase in provider hours of only 3.1% resulted in a decrease in the proportion of patients who left without being seen by 22.9%. Restricting attention to a 4-day subset of the week during which there was no increase in total provider hours, a reallocation of providers based on the queueing analysis resulted in a decrease in the fraction of left without being seen of 21.7% while the arrival volume increased by 5.5%.

Delays for Inpatient Beds

With the advent of price deregulation and increasing pressure from government, employers and managed care organizations, U.S. hospitals have been forced to focus on cutting costs. Due largely to decreased levels of compensation from Medicare and Medicaid, which account for over 50% of hospital revenues, about 1/3 of all hospitals

have negative operating margins and the vast majority of them struggle to break even [13]. Until the last few years, the number of hospitals had been steadily declining for decades. Many more have downsized, particularly since the mid-1990s. Many of these closures and downsizings have been directly due to the use of target occupancy levels that have been used since the mid-1970s at both the federal and state government level to evaluate and control the supply of hospital beds [14]. As recently as December 2006, a commission set up by Governor Pataki of New York State mandated the closure of almost 20 hospitals and the downsizing of dozens more using their finding of an average occupancy rate of 77% as compared with the “ideal rate of 85%” as their primary evidence of “excess capacity” [15]. This was done without any analyses of the impact on delays for emergency or inpatient care. At the institutional level, low occupancy levels are often viewed as indicative of operational inefficiency and potential financial problems. So hospital administrators generally view higher occupancy levels as desirable.

As mentioned above, the most frequently cited reason for ED overcrowding is the lack of inpatient beds and, in particular, critical care beds. Yet, ICUs and other critical care units are usually very small and intentionally operated at high levels of utilization so as to be “cost-efficient.”

In a study of the impact of target occupancy levels on delays for time-sensitive conditions [16], the basic $M/M/s$ model was used to estimate delays for ICU beds for all relevant hospitals in New York State and demonstrate the potentially adverse impact of using simple occupancy level guidelines to determine hospital bed needs. The assumption of a Poisson arrival process is reasonable in this situation since many arrivals to ICUs come through the ED and these arrivals have been shown to be well-approximated by this process, see, for example, [11].

The average size of the units in the New York hospitals was only 15 beds and the mode was 10 beds, and the data showed an average occupancy of 75%. Using the traditional criterion of hospital occupancy levels, many

of these units would be considered to have “excess” beds.

Since patients needing an ICU bed are emergent and any delay can be dangerous, we used probability of delay as our metric of performance. This measure was also chosen because it depends only on size and server utilization which were available from New York State Institutional Cost Reports. Thus, the number of beds needed to meet any delay target could be easily computed.

Adopting a standard of a maximum probability of delay of 10%, the analyses indicated that 112 of the 194 ICUs, or about 58%, were over-utilized. If that target is reduced to 5%, 143 or 74% of the units were too small to handle their experienced workloads; for a 1% target, 175 or over 90% were of inadequate size. These estimates are likely to be conservative for several reasons. First, in an analysis of intensive care units at Beth Israel Deaconess in Boston, the coefficient of variation of length-of-stay ranged from 1.1 to 1.6 [17], suggesting that the $M/M/s$ assumption of exponential service times leads to underestimates of actual congestion. Second, several of the hospitals had multiple divisions or locations, and the reported units are sometimes the sum of two or more smaller units. Third, in many larger hospitals, there are several types of ICUs (e.g., medical, surgical, neurological, and cardiac). Therefore, some of the unit sizes reported in these data likely represent the combined size of smaller, specialized units. It is also important to note that the average reported length-of-stay in these units was almost 18 days, so that when delays occur, they are likely to be long. This observation is consistent with reports by ED administrators.

It is also important to note that in performing these types of simplistic analyses, the data used is not really reflective of the true demands for the units being studied. For example, because many ICU units are often fully occupied, the hospitals in which they are housed will likely be on “critical adult” diversion on occasion and so their occupancy levels are based on some unmet demands. Another reason this may occur is that when patients are waiting in the ED for an ICU bed, less seriously ill patients in the ICU unit

may be transferred to a “step-down” unit to make room for the more needy new arrivals, hence reducing the length-of-stay.

The above analyses demonstrate that even simple models can be useful in identifying capacity problems in hospitals. But discussions with administrators and physicians who work in critical care units point to several other ways in which queueing models can be used to help alleviate emergency room delays due to unavailability of beds. First, queueing analyses can be used to show the impact of consolidating smaller, specialized nursing units into larger ones. An example of this can be seen in Green and Nguyen [17]. Since in many hospitals, the longest ED delays are for the most critically ill patients, it might be advisable to consider consolidating some of the units for which these delays are consistently long. For example, in some hospitals, stroke monitoring units have been established for patients who are victims of serious ischemic strokes. These units are characterized by more intensive nursing levels and telemetry for monitoring the stroke patients who stay in the unit until they are stabilized and can be transferred to a general neurological unit. A current study on the management of stroke patients in several hospitals has revealed anecdotal evidence that ED delays for stroke patients are often very long, jeopardizing long-term medical outcomes. Therefore, it might be sensible to consider caring for stroke patients in a neurological ICU which is also used for patients with other critical neurological problems such as head trauma, as is done in many hospitals without dedicated stroke units. Increasing the flexibility of beds can significantly decrease delays and queueing analysis can be used to estimate the magnitude of the improvement.

Other types of OR models can be used to identify admissions policies for ICUs. The decision to place a new patient into an ICU or critical care bed is a very subjective one and there are no professional or hospital guidelines. While for many patients the need for a critical care bed is clear, for many others, it is not and admission may be determined by whether or not a bed is available. Shmueli

et al. [18] developed a model for optimizing admissions to an intensive care unit based on a policy of admitting only patients whose expected incremental survival benefit from being treated in the ICU exceed some hurdle. Using data from a Jerusalem University hospital, they demonstrated that such a policy could result in saving 17.9% more lives relative to using a first come first served policy. They also explored the relative performance of policies based on both expected benefit and bed availability and showed that these had only a minimal impact on the number of lives saved.

Delays Due to Unavailability of Nurses

There has been a great deal of discussion and debate in the professional nursing world as well as in state legislatures, about how many nurses are really needed in hospitals. While nursing ratios are still the most common methodology for determining nursing levels, the old guidelines of 8:1 have been challenged with the result that in 2004, California implemented the first state law mandating minimum nurse to patient staffing levels of 1 to 6 in general medical-surgical units [19]. Other states are contemplating similar legislation. However, there have been many arguments made against the use of mandated staffing ratios [20]. Opponents of mandated ratios observe that none of the studies of staffing and quality have identified an optimal ratio and that ratios are too inflexible to account for variation in nursing skills and the severity of patients' illnesses.

From an analytical perspective, a clinical unit can be viewed as a finite source queueing system since demands are generated from the inpatients in that unit. However, due to admissions, discharges and transfers, the number of inpatients varies over a shift. Furthermore, each of these changes in inpatient census triggers a demand for nursing care. So in order to identify appropriate nursing levels, it is necessary to model a single hospital clinical unit as a queueing system with two sets of servers: nurses and beds. Though patients are usually assigned to a specific nurse for each shift, it is common practice for any available nurse to attend to a patient if the designated nurse is busy with other

patients. So it is reasonable to assume that both the nursing system and the bed system are multi-server.

Yankovic and Green [21] developed an easy-to-use two-dimensional queueing model for evaluating the impact of any given nursing level on performance measures such as the expected waiting time for a nurse, the probability of being delayed, and other performance indicators. This will enable hospital administrators and nurse managers to determine nurse staffing levels for various units and shifts that best fit their target service standards.

From a policy perspective, the model can be used to demonstrate the potential problems with using the type of mandated nurse to patient ratios legislated by California. Specifically, analyses showed that while a 1:6 nurse to patient ratio may insure a small probability of delay, that is, less than 5%, for nursing demands in a busy clinical unit of 60 beds, an otherwise similar unit with only 30 beds would require a minimum of 1:5 ratio to achieve the same delay performance. This is not surprising for anyone who understands that queueing systems exhibit economies of scale. Less obviously, the results showed that the average length-of-stay can also have an impact on nursing levels required to achieve short delays for care. In particular, since the admissions and discharge processes require a significant amount of nursing time, units with shorter lengths-of-stay will require higher staffing levels than those with longer lengths-of-stay.

Because the model tracks the number of patients in the unit and assumes, as in reality, that a new patient cannot be admitted to the unit unless a nurse is available, the model can be used to estimate the impact of nursing levels on delays for patients waiting in the ED. This is particularly important since nurse unavailability is often overlooked as a factor affecting ED delays. Using the queueing model, delays of patients in the emergency room due to both bed and nurse unavailability can be easily estimated. Figure 1 compares the expected number of patients waiting for a bed in a single clinical

Figure 1. The impact of nurse staffing levels on ED delays.

unit by using a standard $M/M/s$ model representing just bed availability with the performance estimated from using the nurse queueing model. This demonstrates the potential impact of ignoring the effect of nurse staffing on emergency room congestion.

In the ED itself, there are several ways in which queueing and other OR analyses can be helpful in determining the impact of nurse staffing levels. Given the significant degree of variability in patient arrival times, types of problems, and time spent in the ED due to physician delays, testing delays and waits for inpatient beds, a simulation study (see section titled “Simulation Modelling and Analysis” in this encyclopedia) would be very helpful in identifying how patient levels and, therefore, nursing levels should vary by time of day and day of week. Another potentially fruitful study would be in determining how the number of scheduled nurses in each staffing period should be determined given significant absentee levels. This is the subject of a current research project being undertaken by the author.

OTHER POTENTIAL SOURCE OF DELAYS AMENABLE TO QUEUEING ANALYSIS

Though a lack of appropriate inpatient beds is usually cited as the major cause of ED overcrowding, patients often experience delays even when beds are available. In fact, as described in Yankovic *et al.* [7], one of the

two most frequent times for ED overcrowding and hence ambulance diversions in New York City is from midnight to 2 a.m. However, this is the time period when hospital occupancy levels are lowest.

One reason for this seeming anomaly was identified in one large New York hospital where a data collection effort showed that the time between bed assignment and the patient leaving the ED peaked from an average of 2.1h to between 3 and 4h during the midnight to 4 a.m., time interval. Further analysis revealed three potential reasons for this. First, the demand for transports peaked to about 8 patients per hour starting at midnight from a daytime average of about 7. This counterintuitive finding was due to the combination of peak arrival rates that started at about noon and stayed high until early evening, and an average duration of 8.2h between arrival time and bed assignment. However, because ED arrival rates drop to near their lowest during this time, hospital managers had decided that transport staff should be reduced starting at midnight from two to one. In addition, it was found that while the average transport during daytime hours was about 20 min, this increased to 27 min starting at midnight. This was attributed to the fact that during the day, ED transport personnel were used for transporting patients to diagnostic facilities located within the ED as well as to inpatient beds; while at night, when these facilities are closed, personnel were used only for transporting patients to beds. As a result of a queueing analysis that incorporated these factors, the hospital added a transporter during the midnight to 4 a.m., period with a subsequent average decrease of over an hour in transport delays.

In addition to transport personnel, most hospitals reduce other support staff at midnight. Many of these, such as nurses, who are needed to physically receive patients on the floors, housekeepers, who must make sure beds are prepared, and other personnel who are responsible for locating beds, impact ED delays. The above demonstrates the need to properly identify and analyze the impact of time-varying effects of both demands and

processing times throughout the hospital in order to alleviate ED overcrowding.

CONCLUSIONS

Health-care delivery systems are increasingly the subject of political discussions and debates as the United States and other countries struggle to reduce costs and improve quality and access. Much of these discussions center around whether there are too many or too few health-care resources such as inpatient beds, physicians, nurses, and imaging facilities. Unfortunately, politicians and policy professionals are often guided, or misguided, by simplistic frameworks and guidelines that are inappropriate and ignore the potentially dangerous impact on emergency department overcrowding. This was dramatically demonstrated in 1987–88 when New York City experienced a severe and protracted citywide shortage of inpatient hospital beds. During this period, ambulances were routinely turned away from full hospitals and urgently sick patients experienced delays of days waiting for an open bed. This hospital crisis followed a two-year period in which capacity declined by 9% because of new state regulations linking Medicaid reimbursement to achieving occupancy levels of at least 85% to reduce the number of “excess” beds in the city [22].

Queueing theory and other operations research models can and should play a role in these critical discussions and decisions regarding capacity needs and uses. The organization and use of clinical units varies significantly across hospitals and OR analyses are needed to identify best practices. Within the ED alone, there are opportunities to explore the impact of various triage policies and practices, the use of “fast-track” facilities to treat non-urgent patients, the use of “districting” to segregate patients into distinct areas either by type or to facilitate management, and many other new practices being implemented to reduce congestion. Given the growing interest in creating more cost-effective and high quality health care and the increasing prevalence

and ability of health-care information technology systems to collect and provide the needed data, this is a rich area for further exploration.

VALUE FUNCTIONS INCORPORATING DISAPPOINTMENT AND REGRET

LAURA MORETTI
IRENE CRISTOFORI
ANGELA SIRIGU
CNRS, Center for Cognitive
Neuroscience, Lyon, France

Economists have produced remarkable data describing how we make economic choices. Until very recently, the economic approach treated the human brain as a “black box” and suggested mathematical equations to explain behavior during complex decisions. This “rational” approach has been enormously successful at yielding a simplified theory of the brain processes underlying economic strategies.

More recently, the introduction of neuroscience tools (brain imaging techniques, lesion studies, and single-cell recording in nonhuman primates) provided evidence that other variables, such as emotions, can interact with utility-maximization in ways that challenge the standard economic theory [1].

For instance, there is evidence that the subjective impact of experiencing gains or losses is influenced by the counterfactual comparison of obtained and unobtained outcomes [2]. The intensity of an emotional response, which can transform disappointment into painful regret when the outcome of a rejected alternative turns from mildly to highly valuable, has been found to be a better predictor of subsequent choices than expected utility alone [3].

The fundamental role of regret in adaptive behavior and brain mechanisms, through which it affects the decision-making process, has been recently revealed by neuropsychological and neuroimaging studies.

The study conducted in our group by Camille and colleagues in 2004 is the first to show the neural basis of regret during decision making. The authors focused their attention on the orbitofrontal cortex (OFC),

a brain region that lies at the interface between emotion and cognition [4] and so ideally suited to control emotional experience through mechanisms such as counterfactual reasoning. The idea in this study was to test whether this cortical region was crucial to anticipate regret as an emotion that guides advantageous choices.

To this aim, Camille and colleagues adapted an experimental paradigm inspired from the work of Mellers *et al.* [5] to test normal subjects and patients with selective lesions within the OFC. The experimental task required subjects to choose between two gambles, each having different probabilities and different expected outcomes (Fig. 1). At trial start, a spinning arrow appeared; rotated for a variable duration, and then stopped indicating the outcome. Two different feedbacks were provided to subjects: a partial feedback and a complete feedback. In the partial feedback condition, the subject saw only the outcome of the selected gamble, while in the complete feedback condition, outcomes of both the chosen and unchosen gambles were provided. This latter condition was thought to induce regret because subjects could experience not only the financial consequence of their choice but also that of the alternative unselected option. At the end of each trial and after the outcome of the chosen gamble was displayed, participants were also asked to rate their emotional state. Moreover, to obtain a more implicit measure of their emotions, physiological responses (skin conductance responses, SCR) were measured both in patients and in normal subjects.

The results confirmed the hypothesis that emotions experienced for the obtained outcome are modulated by the unobtained outcome. For instance, a disappointment effect was elicited in the partial feedback condition: subjects perceived a loss as more unpleasant and a gain as less pleasant if the unobtained outcome from the same gamble won \$200 instead of losing \$200. This emotional modulation was much stronger in the

complete feedback condition where, knowing the outcome of the rejected alternative triggered the experience of regret. Participants not only reported a strong negative feeling when losing \$50 and the unchosen alternative won \$200, but they also reported being unhappy when gaining \$50 and the other option won more (\$200) (Fig. 2). The different emotional nature of disappointment and regret was revealed by the physiological index of emotional reactivity (SCR): viewing the outcome of the rejected alternative enhanced SCR as compared with viewing

only the outcome of the chosen gamble, thus, revealing that regret could engender a more intense response than disappointment.

The critical finding of this study concerned, however, the pattern of results in patients with OFC lesions (Fig. 3). Patients showed a disappointment effect comparable to control subjects: when losing, patients were indeed somewhat sadder if the unobtained outcome was a large gain than if it was a greater loss, and their SCR demonstrated clear emotional arousal when learning the outcome of the gamble.

Figure 2. Effect of the unobtained outcome of the gamble in partial and complete feedback: (a and c) Mean emotional ratings made by 18 normal control subjects for two obtained outcomes (-50 or 50) as a function of the unobtained outcome (line with square points and symbols: -200 , line with triangle points and symbols: 200) in the partial and complete feedback conditions, respectively. In the partial condition, the unobtained outcome corresponds to the unobtained value of the chosen gamble. In the complete condition it corresponds to the obtained value of the nonchosen gamble. (b and d) Mean emotional ratings made by five orbitofrontal patients in the partial and complete feedback conditions, respectively. Conventions as in a and c. (e) Mean skin conductance response ($\pm$ standard error) of 15 normal subjects measured at the end of arrow rotation, for the conditions in which the unobtained outcome is more advantageous than the obtained outcome (corresponding to the lines with the triangles in the graphs above). Regret is correlated with stronger emotional arousal. (f) Same data for orbitofrontal patients, showing no regret effect. (Source: Reprinted with permission from Camille *et al.* [7]).

Figure 3. Lesion overlap in the OFC for the five patients. Lesion locations were reconstructed from individual MRI scans. The region of common cortical damage is located in the basal and ventromedial sector of the prefrontal cortex and involves Brodmann's areas: 10, 11, 32, 24, 47. (Source: Reprinted with permission from Camille *et al.* [7]).

This suggests that OFC patients were not emotionally unresponsive, and they were somewhat able to think counterfactually on the chosen gamble. Nevertheless, the emotions experienced by these patients were not modulated at all by the feedback of the unchosen gamble, and they seem to experience no regret. Indeed, emotional ratings showed that sadness expressed by the patients at losing \$50 was not more intense if the rejected alternative won \$200, nor the joy felt at winning \$50 was tarnished by seeing that the gain would have been larger if they had selected the alternative gamble (Fig. 2). These results confirmed the hypothesis that the ability to experience regret is mediated by the OFC.

Camille and colleagues went further by investigating how the anticipated emotion of regret influences the entire economic decision process. To this aim they tested a model of choice incorporating disappointment and regret as emotional variables and the expected values of the two gambles.

Noteworthy, the structure of the experiment was defined so that the two gambles always differed in their expected values, but the gamble with the highest expected value won less often on average than the one with the lowest expected value. This was done

to ensure that subjects would experience regret on a sufficient number of trials and so they could learn to choose advantageously by anticipating future emotional reactions and try to avoid negative emotions.

Results of this analysis showed that healthy subjects, after being exposed to several trials in which they experienced regret, began to choose the gambles with probable outcomes likely to produce minimal regret. By contrast, OFC patients persisted in choosing the more risky gamble with a high probability of producing regret.

Thus, regret experience contributes to making advantageous economic choices. The underlying process would involve integrating considerations about future emotional responses to the outcome of choices, that is, anticipating regret and maximizing expected values, allowing subjects to make advantageous decisions. This process would be impaired in patients with a lesion in the OFC. The lack of a counterfactual comparison between the value of a chosen and a rejected alternative would prevent them from anticipating the potential negative consequence of their choices. Consistent with economic models of regret [6], the regret function ψ , which is given by the comparison between the value of choice and the value

of a rejected alternative, would enter into the utility function (U). According to this theoretical model, the utility of an act (e.g., choice of x and simultaneous rejection of y) can be computed as the sum of the expected utility of the chosen act (x) and of the anticipated regret term $\psi(\cdot)$. Camille *et al.* [7] suggested that the integrity of OFC is necessary to incorporate regret function into the decision-making process, that is, into the utility function.

A lesion in the OFC would correspond to a $\psi_{\text{regret}} = 0$; and would cause subjects to make their judgments solely on the basis of what has actually occurred, and not by anticipating the negative consequences of their choices, that is, the regret. Paradoxically, the behavior of OFC-lesioned patients would be more in line with the rational theory, such that their behavior is in agreement with maximization of expected utility [3,7].

The involvement of the OFC in the experience and anticipation of regret and its role in learning processes was better defined in a second experimental study from our group by Coricelli *et al.* [8]. Here we measured the brain activity using functional magnetic resonance imaging (fMRI) while subjects participated in the regret gambling task.

The results revealed that three main regions correlated with the degree of experienced regret, namely the medial OFC region, the dorsal anterior cingulate cortex (ACC), and the anterior hippocampus. The

two latter regions are typically involved in declarative memories and cognition-induced arousal responses. These areas were activated when an outcome was compared with a more advantageous one, and were deactivated when the actual outcome was compared with a less advantageous alternative.

Interestingly, the hippocampal activity would suggest that subjects begin to learn to anticipate regret. This brain region supports indeed a modulation of declarative memory [9], such that after a bad outcome, the lesson to be learnt is: “in the future, pay more attention to the potential consequences of your choices.”

The influence of regret on subsequent choices was confirmed by behavioral data.

In line with the cumulative experience of regret, as regret increased subjects avoided risky choices over time. In fact, they first showed a bias away from choices that may potentially generate regret and, second, showed a bias away from choices that had previously led to negative outcomes. Crucially, these behavioral biases were expressed in a pattern of neural activity at the time of choice. During the time window between the trial onset and subject response, when subjects minimize regret and maximize expected values, an enhanced brain activity was found in the ACC. It is not surprising that this region, usually involved in conflict monitoring [10], is activated

Figure 4. Activity at choice reflecting cumulative regret was found in the medial left amygdale (Amg; coordinates -8 (to -16), -4 , -25) and medial OFC (OFC; coordinates -10 , 40 , -24). (Source: Reprinted with permission from Camille *et al.* [7]).

in such kind of decisions where a conflict between maximizing the expected value and minimizing regret is at stake.

One critical finding of this study concerned the cumulative effect of regret, which makes the subject become more averse to regret over time. This effect was linked to the activity in the OFC and amygdala, the same brain regions that were found activated during the mere regret experience (Fig. 4). Thus, as a result of learning mechanisms, the same patterns of activations related to regret responses seem to be reactivated when subjects choose, thereby making it possible to anticipate the future consequences of his/her choices and therefore is anticipating the future consequences of his/her choices.

Overall, these findings show that a specific brain mechanism is responsible for attributing affective values to the alternative of our choices in terms of current or anticipated emotional experience. These results confirm that specific mechanisms of cognitive control are activated during the choice processes, involving reinforcement or avoidance of the experienced behavior. As such, the experience of regret and its anticipation would promote behavioral flexibility and minimize the negative outcomes of choices.

The interface between theory and experimentation and between mathematical models and brain function provide important insights for the understanding of the processes that underlie economic decision, preferences formation, and learning.

In line with this prospective, Marchiori and Warglien [11] have recently used neural network models that incorporate "regret" to predict the outcomes of games played by humans. They showed that also choices in economic games are better predicted by using regret-based models, than theoretical economic ones.

As the mathematical formalism of economic theories provides new ways of analyzing the neural computations involved in representing decision variables, neuroscientific approaches can contribute greatly to better understanding the cognitive

and emotional underpinnings of economic decision-making, including how people form beliefs about what other people feel or might do.

Overall, the findings reported here show that human choices and decision processes are not exclusively guided by utility considerations. Regret and the sense of responsibility that this complex emotion triggers may be an important factor for our choices and future decisions. These cognitive and emotional mechanisms are deeply rooted in specific brain regions such as the orbitofrontal, the cingulate cortex, and the amygdala.

VARIANTS OF BROWNIAN MOTION

SHANKAR BHAMIDI

Department of Statistics and Operations
Research, The University of North
Carolina, Chapel Hill, North Carolina

PRISCILLA E. GREENWOOD

MCMSC, Arizona State University,
Tempe, Arizona

As explained in the (see ***Brownian Motion and Queueing Applications***), Brownian motion is one of the most fundamental of all stochastic processes. Brownian motion and its variants arise in a wide variety of contexts ranging from scaling limits of other processes to being used directly in models of physical systems. The main aim of this article is to introduce a number of variants of this mathematical object and pave the way for the general study of diffusions in the (see ***Introduction to Diffusion Processes***). Given the enormous range of applications of Brownian motion and its variants, it will not be possible to do justice to even a fraction of the variants of this beautiful process. Rather, we shall choose some particular examples and give the reader an idea of the diverse fields in which such models arise, ranging from queueing theory, stochastic finance, statistical physics, and models of diffusion on fractals. In each example we shall attempt to give some references for a deeper coverage of these topics. As one can imagine, for each of the models in this article, volumes have been filled developing their mathematical properties and areas of applications.

Let us first recall the definition of standard Brownian motion.

Definition 1. [Standard Brownian Motion]. A stochastic process $\{B(t) : t \geq 0\}$ is called standard Brownian motion if it has continuous sample paths with $B(0) = 0$, with stationary independent increments such that for all $0 \leq s < t < \infty$, $B(t) - B(s) \sim N(0, t - s)$.

It follows from the definition that Brownian motion is a Markov process.

For any $\mu \in \mathbb{R}$ and $\sigma > 0$, the process $\{X_{\mu,\sigma}(t) : t \geq 0\}$ defined by

$$X_{\mu,\sigma}(t) = \mu t + \sigma B(t)$$

is called *Brownian motion* with drift μ and variance parameter σ^2 . Figure 1 shows an example of the sample path of this process with positive drift.

REFLECTED BROWNIAN MOTION

A simple variant of Standard Brownian motion, is Brownian motion reflected at some level say the origin, so that it is constrained to be nonnegative. Reflected Brownian motions in one and higher dimensions arise as models of diffusing particles constrained within a region and have been used in a number of different fields, ranging from physiology to nuclear magnetic resonance. See, for example, Ref. 1 for a modern survey of such applications. These variants of Brownian motion are also very important in describing scaling limits of various discrete systems in areas such as queueing theory. While in many advanced settings one uses stochastic differential equations to construct such a process, let us give an example of one simple situation where the reflected process can be explicitly constructed using standard Brownian motion. We start with a motivating example of a simple discrete model, which converges to this process in the limit and then elucidate a bit more on its construction. Much of this section follows [2], which has a nice introduction for the derivation of such limit theorems and their applications in a wide variety of settings in queueing theory.

Consider the following simple model of a buffer of a switch in a large communication network whose role is to process inputs and transmit output. We discretize time into finite intervals called *periods*. For $k \geq 1$, let W_k represent the load on the buffer at the end

Figure 1. Brownian motion with drift $\mu = 2$ and sd $\sigma = 1$.

of period k . During this period suppose the buffer received some random input V_k and processed a deterministic output μ , assuming the buffer size is nonempty and the buffer has something to transmit. If the buffer has infinite capacity then the evolution of the workload is given by

$$W_k = \max\{0, W_{k-1} + V_k - \mu\} \quad (1)$$

while if the buffer has some finite capacity C then

$$W_k = \min\{C, \max\{0, W_{k-1} + V_k - \mu\}\} \quad (2)$$

Assume that the inputs V_k are independent and identically distributed positive random variables with finite variance σ and mean ν . Note that if the deterministic output μ is less than the expected input ν then the load on the buffer quickly increases (by the strong law of large numbers, the load on the buffer at the end of period k would be $W_k \sim k(\nu - \mu)$ as $k \rightarrow \infty$). Thus, suppose we assume that we are in the *critical* regime where the deterministic output μ is exactly equal to the expected input ν . Then since the process

$$\left\{ \frac{1}{\sqrt{n\sigma}} \sum_{k=1}^{\lfloor nt \rfloor} (V_k - \mu) : t \geq 0 \right\}$$

converges to standard Brownian motion, it is natural to postulate that the limit of the workload process in the infinite capacity regime given by Equation (1) is reflected Brownian motion, namely,

$$\left\{ \frac{1}{\sqrt{n\sigma}} W_{\lfloor nt \rfloor} : t \geq 0 \right\}$$

converges as $n \rightarrow \infty$ to Brownian Motion but reflected at 0. It turns out that the natural definition of reflected standard Brownian motion is the following.

Definition 2. [Reflected SBM]. Suppose $\{B(t) : t \geq 0\}$ is standard Brownian motion. Then the process $\{Y(t) : t \geq 0\}$ defined by

$$Y(t) = |B(t)|, t \geq 0$$

is called standard Brownian motion reflected at the origin.

Figure 2 shows a sample path of this process.

Now suppose $B(\cdot)$ is standard Brownian motion and define

$$\tilde{Y}(t) = B(t) - \inf_{0 \leq s \leq t} B(s).$$

Figure 2. Reflected standard Brownian motion.

A deep and powerful result due to Paul Levy implies that this process has the same law as the process $Y(\cdot)$ in Definition 2, see Ref. 3 for a proof of this beautiful result. The advantage of this new construct is that while Definition 2 does not work for the Brownian motion $X_{\mu,\sigma}(\cdot)$ with general drift and variance, Levy's version does generalize. The reflected version at 0 of this process is defined by

$$Y_{\mu,\sigma}(t) = X_{\mu,\sigma}(t) - \inf_{0 \leq s \leq t} X_{\mu,\sigma}(s) \geq 0$$

To see an example of why this construct is so useful, consider the infinite capacity buffer as in Equation (1) but in the near critical regime, that is, with the deterministic output $\mu = \mu_n$ being near the mean $v = \mathbb{E}(V_k)$ in the sense that

$$\mu_n = v + \frac{\alpha}{\sqrt{n}}$$

for some fixed constant α . Then as before, the workload process

$$\left\{ \frac{1}{\sqrt{n}} W_{[nt]} : t \geq 0 \right\} \quad (3)$$

converges to $Y_{\alpha,\sigma}$ as $n \rightarrow \infty$. Such results give us useful information about the macroscopic (large scale) behavior of queues.

Similarly one can study Brownian motion constrained to lie in an interval $[a, b]$ and reflected at the end points. For example, consider the single buffer model but now with the capacity $C = C_n$, a function of n ,

$$C_n = b\sqrt{n}$$

for some constant b . Then the workload process in Equation (3) converges to Brownian motion reflected both at 0 and b .

GEOMETRIC BROWNIAN MOTION

Brownian motion itself is not a good model of various financial constructs. Geometric Brownian motion is a variant of Brownian motion, which has seen tremendous use in the area of stochastic modeling of processes in finance such as prices of stocks. Let us attempt to motivate the (stochastic) differential equation that a stock price process (referred to as $Z(t)$) might satisfy and then see how this process can be expressed as an explicit function of standard Brownian motion.

The starting point is the assumption that for the price of a stock, the infinitesimal change in the price is given by two components.

Figure 3. Geometric Brownian motion started at 1 with $\mu = 3$ and $\sigma = 1$.

1. *Deterministic Component.* For the price of the stock one expects constant expected value of return on the investment so that in a small time interval $[t, t + dt)$, the change in the price is proportional to $\mu Z(t)dt$ where μ is a constant measuring the rate of return.
2. *Stochastic Volatility.* The price of the stock is buffeted by a large number of small random factors in any time interval, and the higher the price, the more volatile is the price. This is modeled by thinking of the change in the stock price in a small interval due to random factors as being proportional to $\sigma Z(t)(B(t + dt) - B(t))$, where $B(\cdot)$ is standard Brownian motion.

This intuition yields the equation

$$dZ(t) = \mu Z(t) dt + \sigma Z(t) dB_t. \quad (4)$$

For any arbitrary starting value $Z(0)$, using Ito calculus, one can check that the process

$$Z(t) = Z(0) \exp \left[\left(\mu - \frac{\sigma^2}{2} \right) t + \sigma B_t \right]$$

satisfies Equation (4) and it is called *geometric Brownian motion*. A good reference for more intuition behind the definition of this process is Ref. 4. Note that when $\mu > \sigma^2/2$, the process tends to infinity, while for $\mu < \sigma^2/2$ this process goes to 0, as illustrated in Figs 3 and 4 respectively.

Geometric Brownian motion plays an important part in the famous Black–Scholes formula, derived in the context of option pricing in finance. We refer the interested reader to Chapter 12 of Ref. 4 and associated references for further information. For an in depth look at the mathematical aspects of general exponential functionals of Brownian motion and applications of these in various mathematical models in stochastic finance [5].

BROWNIAN BRIDGE

The Brownian bridge $\{X(t)\}_{0 \leq t \leq 1}$ sometimes referred to as *tied down Brownian motion* is a fundamental object that arises in a number of applications of Brownian process theory in statistics, in particular, the important Kolmogorov–Smirnov test. Intuitively one thinks of the Brownian bridge as standard Brownian motion *conditioned to come back to 0* at time 1, that is, conditioned on $B_1 = 0$. While this conditioning event has measure

Figure 4. Geometric Brownian motion started at 1 with $\mu = 0$ and $\sigma = 2$.

0, there are a number of ways to make the notion precise. For example, for any $\epsilon > 0$ one could look at the measure of $\mathbb{P}^\epsilon(\cdot)$ of standard Brownian motion conditioned on $|B_1| \leq \epsilon$ (an event with positive probability) and then show that $\mathbb{P}^\epsilon$ are a tight sequence of probability measures on the sequence space $\mathbb{P}^\epsilon(\cdot)$ with a unique limit as $\epsilon \rightarrow 0$ [6]. Alternatively one could solve the stochastic differential equation

$$\begin{aligned} dX(t) &= \frac{-X(t)}{1-t} dt + dB(t), \\ 0 \leq t \leq 1, X_0 &= 0, \end{aligned} \quad (5)$$

where $B(\cdot)$ is standard Brownian motion. For this approach, see Chapter 5 of Ref. 3. Intuitively Equation (5) suggests that as time gets closer to 1, the process is forced to approach 0. One can check that the Brownian bridge as defined by solving Equation (5) has the same distribution as the process

$$\{B(t) - tB(1)\}_{0 \leq t \leq 1}, \quad (6)$$

where $\{B(t) : 0 \leq t \leq 1\}$ is, as usual, a standard Brownian motion. Figure 5 shows a sample path of this process.

The first important property of Brownian bridge, which is a direct consequence of Equation (6), is that it is a Gaussian process

(i.e., a process all of whose finite-dimensional distributions are Gaussian). The mean of the Brownian bridge is given by

$$\mathbb{E}(X_t) = 0 \quad \text{for } 0 \leq t \leq 1,$$

and its covariance function is

$$\rho(s, t) := \text{Cov}(X_s, X_t) = s(1-t), \quad 0 \leq s \leq t.$$

Kolomogorov–Smirnov Test

As mentioned in the introduction, the Brownian bridge is extremely important in empirical process theory in statistics. Here we give the reader an idea of how it arises as the scaling limit of fluctuations of empirical distribution functions about their true value. The setting is as follows: Suppose $\{Y_i\}_{1 \leq i \leq n}$ are independent and identically distributed random variables having a continuous distribution function $F(\cdot)$. Consider the empirical distribution function

$$F_n(t) = \frac{1}{n} \# \{j : Y_j \leq t\}, \quad t \in \mathbb{R}.$$

Define the process $Y_n(t)$

$$Y_n(t) := \sqrt{n}(F_n(t) - F(t)), \quad t \in \mathbb{R},$$

Figure 5. Brownian bridge.

and note that $\lim_{t \rightarrow \pm\infty} Y_n(t) = 0$. Using the standard central limit theorem it is not hard to see that the finite dimensional distributions of the process $Y_n(\cdot)$ converge to those of the process $Y(\cdot)$

$$Y(t) := X(F(t)),$$

where $X(\cdot)$ is the Brownian bridge. One can strengthen the above finite-dimensional convergence to weak convergence of $Y_n(\cdot)$ as a process to $Y(\cdot)$ and, in particular, show that

$$\sup_{t \in \mathbb{R}} |Y_n(t)| \xrightarrow{d} D := \sup_{0 \leq s \leq 1} |X(s)|$$

as $n \rightarrow \infty$. Another calculation implies that for any $x > 0$

$$\mathbb{P}(D > x) = 2 \sum_{k=1}^{\infty} (-1)^{k-1} e^{-2k^2 x^2}.$$

These facts are often used to test the hypothesis that a sample $\{Y_i\}_{1 \leq i \leq n}$ comes from some specified continuous distribution F .

The above is just one very small corner of the vast field of empirical process theory. We refer the interested reader to Ref. 7 or 8 for comprehensive treatments of this subject.

ORNSTEIN–UHLENBECK PROCESS

The Ornstein–Uhlenbeck process arises very naturally in various physical systems with resistance, such as the motion of a particle in a fluid facing friction or the vibration of a string. Let us first describe such a model in more detail, then state some rigorous properties of this process, and finally give references. Many of the physical motivations are paraphrased from Chapter 5 of Ref. 9. We shall be a little imprecise when describing the mental picture one has behind this process.

Let $V(t)$ denote the velocity at time t , of a one-dimensional particle with mass m , suspended in a fluid with coefficient of friction β . The frictional force is directly opposite to the direction of motion and is proportional to the magnitude of the velocity. In the absence of random collisions from other molecules in the fluid, the motion of the particle can be described by the differential equation

$$m \frac{dV(t)}{dt} = -\beta V(t).$$

However, the particle experiences a large number of random collisions from other molecules, so that the acceleration has both the above deterministic component and a random component. Assuming that the

particle experiences a large number of very small collisions in any small interval of time $[t, t + dt)$, invoking the central theorem, we conclude that the random component in the change in velocity should be a normal random variable with mean 0 and variance σdt for some constant σ , that is,

$$V(t + dt) - V(t) \sim -\beta V(t) dt + \sigma \mathcal{N}(0, dt),$$

where $\mathcal{N}(0, dt)$ is a normal random variable independent of the present velocity $V(t)$. Now note that (again at a heuristic level), for standard Brownian motion we have

$$B(t + dt) - B(t) = \mathcal{N}(0, dt),$$

so that the above equation can be written as

$$dV_t = -\beta V(t)dt + \sigma dB(t). \quad (7)$$

The solution of the *stochastic* differential equation (7) is the Ornstein–Uhlenbeck process. Each increment of the Ornstein–Uhlenbeck process can be viewed as a combination of a restorative force proportional to the present state of the system and a random perturbation. Solving the above equation with the starting value $V(0)$ having a normal distribution with mean 0 and variance σ^2/β , one can check that $V(t)$ is a stationary Gaussian process, with mean 0 and covariance function

$$\rho(s, t) := \text{Cov}(V(t), V(s)) = \frac{\sigma^2}{2\beta} e^{-\beta|t-s|}. \quad (8)$$

Note that the correlations between time points fall off exponentially in $|t - s|$.

As a model in applied probability, this process arises in a diverse number of contexts ranging from modeling neurons [10], to finance where it has been used in models of evolution of interest rates such as the famous Vasicek model (see the original paper [11] or [12]). For a beautiful introduction to the physical motivations behind the definition of the Ornstein–Uhlenbeck process as described in the beginning of this section, see Chapter 9 of Ref. 13 or Ref. 14.

MULTIDIMENSIONAL BROWNIAN MOTION

Another simple extension of standard Brownian motion is multidimensional Brownian motion. For fixed $d \geq 1$, if $\{B^{(i)}(\cdot) : i \geq 1\}$ are independent Brownian motions then the d -dimensional random process

$$\mathbf{B}(t) = (B^{(1)}(t), B^{(2)}(t), \dots, B^{(d)}(t))$$

is called the d -dimensional Brownian motion. This process arises not only as a model of a particle diffusing through d -dimensional space but has also given rise to beautiful mathematics. In addition it has proven to be very important in applied settings, including modeling of particles diffusing in various physiological and biological settings [1] and in areas such as queueing theory. For example, in two dimensions, the conformal invariance of Brownian motion can be used in a simple proof of the fundamental theorem of algebra. The following argument is based loosely on Ref. 15. Let $Z(t)$ denote complex Brownian motion,

$$Z(t) = B^{(1)}(t) + iB^{(2)}(t),$$

where $i = \sqrt{-1}$. One of the fundamental properties of this process is that for any holomorphic (i.e., differentiable) function f , the process $f(Z(\cdot))$ can be expressed as a continuous time change of another complex Brownian motion, namely, there exists a complex Brownian motion Z' such that

$$f(Z_t) = Z'_{C_t},$$

where

$$C_t = \int_0^t |f'(Z_s)|^2 ds.$$

In particular since the process Z' gets arbitrarily close to the origin, this implies that if $f(\cdot)$ is a polynomial (which automatically implies f is holomorphic) then there exists a point z such that $f(z) = 0$, and thus the polynomial has at least one root. This is the fundamental theorem of algebra. Of course this is just a very simple example of the kind of calculations that are possible. We refer the interested reader to Ref. 16 for a

beautiful mathematical exposition of various path properties of multidimensional Brownian motion (mainly focusing on the planar two-dimensional setting) as well as Chapter 9 of Ref. 17.

Recall that in the section titled “Reflected Brownian Motion”, we explored reflected versions of Brownian motion that arose in the context of a simple model of infinite capacity buffers. Reflected versions of the multidimensional process arise in more complicated models of queueing networks such as tandem queues. Such processes are usually constructed via stochastic differential equations. Even showing the existence of such processes is nontrivial in a number of settings. See Ref. 18 or the comprehensive books [2,19] for various applications in queueing theory and the mathematical issues that arise in constructing such processes in general domains.

BROWNIAN EXCURSIONS

The concept of Brownian excursions away from 0 is easy to talk about but much more nontrivial to define mathematically. The set of times

$$\mathcal{O} = \{t : B_t = 0\}$$

is a perfect set, that is, each point is a limit point of other such points. However if one looks at $\mathcal{O}^c$, then due the path continuity of Brownian motion, this set is open and can be expressed as a disjoint countable union of open intervals $\cup_j (a_j, b_j)$. Owing to the extreme irregularity of $\mathcal{O}$, we cannot speak about the “first” excursion of Brownian motion away from 0, the second, and so on. The set of excursions is the set of path segments between the 0-points, that is, we decompose the path of Brownian motion according to its excursions:

$$\{B((t + a_j) \wedge b_j) : t \geq 0\}$$

each of which is a random element of the set of continuous functions started at 0 and ending at 0 in finite time without visiting 0 in between these two times. It turns out that these paths plotted against the local time of Brownian motion at 0 form a *Poisson* point process, with an explicitly computable intensity measure called the *Ito Excursion*

measure. This fact leads to a very powerful technique for exploring the path properties of Brownian motion. Further, if one wants a notion of Brownian motion, started at 0 and conditioned to return to 0 at time $t = 1$ and always above the x axis, then a natural candidate for such an object is the following: fix any time $t > 0$. Almost surely, $B_t \neq 0$. Let α_t be the last time *before* t that the Brownian motion was at 0 and let β_t be the first time *after* t that Brownian motion visits 0 and let $\gamma_t = \beta_t - \alpha_t$ be the length of this excursion. Then a natural candidate for this process

$$e(s) = \frac{1}{\sqrt{\gamma_t}} |B(\alpha_t + s\gamma_t)|, \quad 0 \leq s \leq 1.$$

Owing to the time and scale invariance properties of Brownian motion, the choice of the fixed time t is of no consequence.

Let us give an example of how this process arises as the scaling limit of discrete random objects and thus gives an enormous amount of asymptotic information about these random structures. Trees and random models of trees play a very important role in many branches of science, ranging from algorithms in computer science to genealogies in biology.

See Fig. 6 for an example of a planar tree and a coding of this tree by a function that represents the distance traveled at any time by an individual walking at rate 1 along the boundary of the tree in lexicographical order, starting from the root (i.e., in the direction of the arrows). Now given a random tree (e.g., the uniform measure on all planar trees on n vertices), in many situations we are interested in understanding the asymptotics of such models as $n \rightarrow \infty$. Note that the contour process coding of a tree is a process that starts at 0 and eventually returns to 0 in $2(n - 1)$ steps without ever going below the x axis. For a random tree, one gets a random function satisfying these properties. What is more difficult, but is now a classical result, is that for a wide range of random tree models, the contour process properly rescaled in time and space converges to the standard Brownian Excursion. See Refs 20 and 21 or the comprehensive Ref. 22 for applications to a diverse number of models from combinatorics ranging from random trees to random graphs and random maps.

Figure 6. Planar tree on 10 vertices and the corresponding contour process.

This fundamental process and its variants such as multidimensional local time, Brownian excursions conditioned on its own local time, and nonintersecting Brownian excursions have arisen in many other diverse contexts ranging from applications in finance such as Parisian options Ref. 23, to mathematical studies of the fine scale structure of multidimensional Brownian motion [16]. For a textbook treatment of this process see Ref. 24, while Refs 25 and 26 give nice introductory treatments.

FRACTIONAL BROWNIAN MOTION

In many applications one is interested in constructing a stochastic model of how a time series evolves over time, e.g. the amount of traffic flowing through a link in a very large data transmission network such as the Internet, various economic time series such as speculative prices, and so on. Models such as the Ornstein–Uhlenbeck process defined in the section titled “Ornstein–Uhlenbeck Process” prove to be insufficient for such applications. Equation (7) implies that for the Ornstein–Uhlenbeck process, the correlation between $V(t)$ and $V(t+h)$ drops down exponentially quickly. This is not the case for many empirically observed time series, where strong temporal correlations are observed over long periods of time, staying above or below prescribed levels for much longer than one would expect under the assumptions

leading to the construction of processes such as the Ornstein–Uhlenbeck process.

Fractional Brownian motion is a variant of Brownian motion, which attempts to fill this gap. The process depends on a parameter H which controls how quickly the correlations decay. For any $0 < H \leq 1$, fractional Brownian motion $\{B_H(t) : t \in \mathbb{R}\}$ is a Gaussian process with mean 0 and covariance function given by

$$\rho_H(s, t) = \frac{1}{2} (|s|^{2H} + |t|^{2H} - |t - s|^{2H}) \quad (9)$$

Note that $H = 1/2$ corresponds to usual standard Brownian motion.

For any $H \in (0, 1)$ this process has continuous but nondifferentiable sample paths with stationary increments (i.e., for any h , the distribution of $B_H(t+h) - B_H(t)$ depends only on h and not on t). The paths of these processes get smoother as H increases from 0 to 1. One can see this by looking at the above covariance function given by Equation (8) and noticing that for any $s > 0$ and any fixed t , the consecutive increments $B_H(t+s) - B_H(t)$ and $B_H(t+2s) - B_H(t+s)$ are negatively correlated for $H < 1/2$ so that consecutive increments have opposite signs, while for $H > 1/2$ these increments are positively correlated. See Figs 7 and 8 for examples of the roughness of the sample paths for $H < 0.5$, while see Figs 9 and 10 for the relatively smoother sample paths for $H > 0.5$.

Another very important property of this process is that it is self-similar with index H , that is, for any fixed $a > 0$

Figure 7. Fractional Brownian motion with Hurst parameter 0.1.

Figure 8. Fractional Brownian motion with Hurst parameter 0.35.

$$\{B_H(at)\}_{t \in \mathbb{R}} = a^H \{B_H(t)\}_{t \in \mathbb{R}}.$$

To get an intuition as to how such correlations arise and how this process arises due to long-range correlations between increments, we quote the following result from Ref. 27. Suppose $X_k = \sum_{j=-\infty}^{\infty} c_{k-j} \eta_j$, where $\{\eta_j\}_{j \in \mathbb{Z}}$ are independent and identically distributed mean 0 and finite variance and the constants satisfy $\sum_{j=-\infty}^{\infty} c_j^2 < \infty$. Suppose we define

the random walk $S_n = \sum_{k=1}^n X_k$ for $n \geq 1$. If $\text{Var}(S_n) = n^{2H} L^2(n)$ for $0 < H < 1$ and $L(\cdot)$ is a slowly varying function at infinity, then

$$\frac{1}{n^H L(n)} \sum_{k=1}^{\lfloor nt \rfloor} X_k \rightarrow B_H(t)$$

in the sense of finite-dimensional convergence.

Figure 9. Fractional Brownian motion with Hurst parameter 0.75.

Figure 10. Fractional Brownian motion with Hurst parameter 0.95.

While this process had already arisen in the work of Kolmogorov, it was Mandelbrot and his coworkers who formulated this as a good model for many processes that arise in various applications such as finance and hydrology [28–30]. See Ref. 31 for a comprehensive account of the mathematical properties of this process, its history, and its wide range of applicability.

BROWNIAN SHEET

Almost all the processes that have been introduced in this article are indexed by time, that is, are of the form X_t for $t \in \mathbb{R}^+$. However, in the applied context, one is often interested in “Brownian processes” that are indexed by more general sets. One of the most famous of such examples is the Brownian sheet. We

shall first introduce this model, then mention how this can be viewed as the continuum limit of discrete processes (similar to viewing the Brownian motion as the continuum limit of random walks), and then give further references. We shall define the simplest version of this model, namely, the *one*-dimensional version.

The Brownian sheet with values in $\mathbb{R}$ is a two-parameter, centered (i.e. mean 0), Gaussian process $\{B(s, t) : s, t \geq 0\}$ with covariance function given by

$$\begin{aligned} \mathbb{E}(B(s, t)B(s', t')) \\ = \min(s, s') \min(t, t'), s, s', t, t' \geq 0. \end{aligned}$$

The above process can be viewed as the scaling limit of a discrete random field on the planar two-dimensional lattice. Consider $\mathbb{Z}_+^2 = \{(i, j) : i, j \geq 0\}$ and let $\{\eta_{ij} : i, j \geq 0\}$ be an independent and identically distributed array of random variables with mean μ and finite variance σ^2 . One could think of η_{ij} as the amount of insect damage at site i, j in a large forest. Thus for any $n, m \geq 0$

$$S(n, m) = \sum_{0 \leq i \leq n} \sum_{0 \leq j \leq m} \eta_{ij}$$

represents the total insect damage in the rectangle with opposite vertices $(0, 0)$ and (n, m) . By the central limit theorem, for any fixed (s, t) the fluctuations of the above random field satisfy

$$\frac{S(\lfloor Ns \rfloor, \lfloor Nt \rfloor) - N^2 st \mu}{\sigma^2 N} \xrightarrow{d} B(s, t)$$

as $N \rightarrow \infty$ and in fact we have finite-dimensional convergence of the processes $Z_N(\cdot, \cdot)$ defined as

$$Z_N(s, t) = \frac{S(\lfloor Ns \rfloor, \lfloor Nt \rfloor) - N^2 st \mu}{\sigma^2 N}, s, t \geq 0$$

to the one-dimensional Brownian bridge as $N \rightarrow \infty$. Under various assumptions one can show that the above convergence of finite-dimensional distributions can be strengthened to weak convergence of the two-dimensional processes.

It appears that this process was first constructed due to motivations from statistics,

in particular, to construct continuous models of analysis of variance [32]. For more on the early motivations and results about this process we refer the interested reader to the papers of Pyke [33, 34]. For a readable modern account see Ref. 35; for a more comprehensive textbook treatment see Ref. 36. Finally, for fascinating connections between this process and an analysis of models of the stochastic wave equation see Chapter 1 of Ref. 37.

OTHER IMPORTANT VARIATIONS

We conclude this article by mentioning a few other variants of Brownian motion, which have proven to be enormously useful in modeling various physical systems, especially at criticality but for which providing a full description is well nigh impossible in an introductory article of this nature.

Brownian Motion on Other State Spaces

Most of the processes that we have looked at above relate to Brownian motion or associated diffusions on the real line or in the Euclidean setting. However, there is a tremendous amount of interest, especially in the physics literature in formulating, rigorously constructing, and analyzing models of diffusion on more general spaces of disordered media, including various fractals such as the Sierpinski gasket illustrated in Fig. 11. The usual model of Brownian motion in Euclidean space could represent a model of transport and flow through a regular crystalline structure. However, many of the materials that physicists consider are far from regular. Physical structures such as porous fractured rock structures and superionic conductors are disordered media. The behavior of diffusing particles in such media is quite different from usual Brownian motion. For example while the usual random walk in the plane scales like $\sqrt{n}$, in the sense that the typical distance of a particle from its starting point after n steps is of the order of $\sqrt{n}$, many models of diffusion in such disordered media show “anomalous diffusion” in the sense that the distance traveled after n steps scales as some other power, n^β . See Ref. 38 for a fascinating survey of a

Figure 11. Sierpinski triangle.

wide array of models and settings that arise from physical motivations, while see Ref. 39 and the references therein for a survey level treatment of the rigorous mathematical results that one can derive in these contexts and connections to other techniques such as the connection between random walks and electrical networks. For diffusion models on general tree-like fractals see Ref. 40 or the comprehensive set of lectures [41].

Schramm–Loewner Evolution

One of the reasons Brownian motions and simple variants such as reflected Brownian motion are so important is that they arise as scaling limits in many important models, such as random walks and queueing systems and thus allow us to understand the macroscopic (large scale) structure of such processes. Statistical physicists are interested in the macroscopic properties of various two-dimensional systems at criticality (a parameter value at which the behavior of the system abruptly changes), including ferromagnetic systems described by the Ising and Potts model and polymer molecules.

Schramm–Loewner evolutions are a one-parameter family of growing random fractal curves in two dimensions indexed by a parameter κ grown using standard one-dimensional Brownian motion and Loewner

chains from complex analysis. The stochastic version was invented by Oded Schramm [42]. These random planar curves have proven to be enormously useful as scaling limits of many fundamental discrete planar models in two dimensions. Although it will be too difficult to describe the actual process, let us give one concrete but easily describable discrete process, whose scaling limit is such a random planar curve.

Loop Erased Random Walk

Consider the discrete integer lattice $\mathbb{Z}^2$. Since we want to understand macroscopic properties of a large random object, consider for any fixed $\delta > 0$ the graph $\delta\mathbb{Z}^2$. Let D denote the disc of unit radius in $\mathbb{R}^2$ and consider the graph $H_\delta = D \cap \delta\mathbb{Z}^2$. Now consider a simple random walk on H_δ , started from the origin and run until the first time it hits the boundary of H_δ , and let T_δ denote this time. Suppose the path of random walk is $(S_0, S_1, \dots, S_{T_\delta})$. Note that for this path, it is quite possible that there will be times when the path will intersect itself, namely, k times such that there exists $m < k$ such that $S_m = S_k$. The *loop erasure* of this path is defined as the erasure of the loops of this path in chronological order. More precisely, define $L_0 = S_0$ and for each $j \geq 0$ define $n_j = \max\{k \leq T_\delta : S_k = L_j\}$ and define $L_{j+1} = S_{n_j+1}$. We continue this

process till $j = \sigma$ such that $L_\sigma = S_{T_\delta}$. The loop erased path is given by $(L_1, L_2, \dots, L_\sigma)$.

The loop erased random walk is an extremely important process, arising in diverse areas of combinatorics and statistical physics, including the generation of spanning trees uniformly at random from graphs. In the above context, one is interested in what happens to the macroscopic (large-scale) structure of the path as the mesh size δ goes to 0. It turns out that as $\delta \rightarrow 0$, the path of loop erased walk converges to a Schramm–Loewner evolution with $\kappa = 2$. We refer the reader to Ref. 43 (by Wendelin Werner who eventually won the Fields medal for his work in this area), or Ref. 44 for an introduction to this rapidly growing field and for the diverse number of contexts where this process arises (or is conjectured to arise) as the scaling limit.

VARIATIONAL INEQUALITIES

IGOR V. KONNOV
Department of System Analysis
and Information Technologies,
Kazan University, Kazan,
Russia

BASIC DEFINITIONS

Let X be a convex set in the n -dimensional Euclidean space $\mathbb{R}^n$ and let $F : X \rightarrow \mathbb{R}^n$ be a mapping. Then we can define the *variational inequality* (VI): Find $x^* \in X$ such that

$$\langle F(x^*), x - x^* \rangle \geq 0 \quad \forall x \in X. \quad (1)$$

Investigation of VI as a separate problem is associated with the works of Fichera [1] and Stampacchia [2]. They introduced VIs for studying certain problems in mathematical physics; see also Duvaut and Lions [3] and Kinderlehrer and Stampacchia [4] for more details. At the same time, there exist several earlier works in different fields which contain similar problem formulations. For instance, the well-known linear programming problem [5] can be treated as VI with the constant mapping F . Afterwards, a great number of applications of VIs appeared in economics, operations research, telecommunications, and many other fields [6–11]. Now VI is treated as the differential form of general equilibrium conditions [12]. The theory and methods for VIs are investigated very extensively and great advances were made recently in this field [10,11,13,14]. In this article, we intend to describe some of these results. We also discuss their possible extensions for the multivalued case.

THEORETICAL BACKGROUND

In this section, we consider VI (1) under the standing assumptions that X is a nonempty, convex, and closed set in $\mathbb{R}^n$ and that

$F : X \rightarrow \mathbb{R}^n$ is a continuous mapping. Then we can deduce the existence of a solution for Equation (1) from the Brouwer fixed point theorem if we additionally suppose X is bounded [4]. If the set X need not be bounded, we have to utilize the so-called coercivity conditions.

Theorem 1 [15,16]. *Suppose that there exists a nonempty bounded subset Y of X such that for every $x \in X \setminus Y$ there is $y \in Y$ with $\langle F(x), x - y \rangle \geq 0$. Then VI (1) has a solution.*

More general existence results are contained, for example, in papers [17–21].

We now recall some norm monotonicity concepts for mappings.

Definition 1. A mapping $Q : X \rightarrow \mathbb{R}^n$ is said to be

- (a) *strongly monotone* with modulus $\tau' \geq 0$ if, for each pair of points $x, y \in X$, it holds that

$$\langle Q(x) - Q(y), x - y \rangle \geq \tau' \|x - y\|^2;$$

- (b) *strictly monotone*, if, for each pair of points $x, y \in X, x \neq y$, it holds that

$$\langle Q(x) - Q(y), x - y \rangle > 0;$$

- (c) *monotone* if, for each pair of points $x, y \in X$, it holds that

$$\langle Q(x) - Q(y), x - y \rangle \geq 0;$$

- (d) *pseudomonotone* if, for each pair of points $x, y \in X$, it holds that

$$\langle Q(y), x - y \rangle \geq 0 \quad \text{implies}$$

$$\langle Q(x), x - y \rangle \geq 0;$$

- (e) *co-coercive* (or *inverse strongly monotone*) with modulus $\tau'' > 0$, if, for each pair of points $x, y \in X$, it holds that

$$\langle Q(x) - Q(y), x - y \rangle \geq \tau'' \|Q(x) - Q(y)\|^2.$$

Clearly, we have (a) $\implies$ (b) $\implies$ (c) $\implies$ (d), and (e) $\implies$ (c). In the affine case $Q(x) = Ax - b$ is (strictly, strongly) monotone if and only if A is a positive (definite) semidefinite matrix. In the differentiable case, the monotonicity concepts are associated with the Jacobian properties [10, Proposition 2.3.2]. Also, each co-coercive mapping with modulus τ'' is Lipschitz continuous with constant $1/\tau''$, and each strongly monotone and Lipschitz continuous mapping is co-coercive, but the reverse assertions are not true in general [22]. Clearly, co-coercivity is equivalent to strong monotonicity of the inverse mapping. Concerning pseudomonotonicity [23], see also Hadjisavvas *et al.* [24] for further development of generalized monotonicity. The monotonicity properties enable us to specialize existence and uniqueness results.

Proposition 1.

- (i) If F is strictly monotone, then VI (1) has at most one solution.
- (ii) If F is strongly monotone, then VI (1) has a unique solution.

It is known that VI (1) is closely related to the following problem of finding $x^* \in X$ such that

$$\langle F(x), x - x^* \rangle \geq 0 \quad \forall x \in X. \quad (2)$$

Problem (2) seems to have appeared first in Debrunner and Flor [25] and may be termed as the *minimax dual* formulation of VI (in short, DVI); see, for example, Konnov [12] for more details. We denote by X^* (respectively, by X^d) the solution set of problem (1) [respectively, problem (2)]. Under the assumptions made, the set X^d is convex and closed. The following assertion is a slightly extended form of the Minty lemma [26], utilizing the pseudomonotonicity.

Proposition 2.

- (i) It holds that $X^d \subseteq X^*$.
- (ii) If F is pseudomonotone, then $X^* \subseteq X^d$.

Further development of this direction can be found, for example, in papers [14,18,19,24]. Besides, most results above can be extended to infinite-dimensional spaces; see papers [16,18–20,24] for more details.

RELATED PROBLEMS

It is easy to see that VI (1) with $X = \mathbb{R}^n$ reduces to the equation

$$F(x^*) = 0.$$

If X is a convex cone in $\mathbb{R}^n$, VI (1) reduces to the *complementarity problem* (CP)

$$x^* \in X, F(x^*) \in X^*, \langle F(x^*), x^* \rangle = 0,$$

where $X^* = \{z \in \mathbb{R}^n \mid \langle x, z \rangle \geq 0 \quad \forall x \in X\}$ is the conjugate cone to X [27]. Conversely, in the case when the feasible set is defined by convex functions VI (1) can be reduced to CP via the Karush–Kuhn–Tucker optimality conditions [6,11].

Next, let T be a continuous mapping from a convex set X into itself. Then the *fixed point problem*, which is to find a point $x^* \in X$ such that

$$x^* = T(x^*) \quad (3)$$

coincides with VI (1), where

$$F(x) = x - T(x); \quad (4)$$

see Kinderlehrer and Stampacchia [[4], Section 3.1].

Definition 2 [4,28]. A mapping $T : X \rightarrow X$ is said to be

- (a) *strongly contractive* with modulus $\kappa \in (0, 1)$ if for each pair of points x, y , we have

$$\|T(x) - T(y)\| \leq \kappa \|x - y\|;$$

- (b) *contractive* if for each pair of points $x \neq y$, we have

$$\|T(x) - T(y)\| < \|x - y\|;$$

- (c) *nonexpansive* if for each pair of points x, y , we have

$$\|T(x) - T(y)\| \leq \|x - y\|.$$

Clearly, we have (a) $\implies$ (b) $\implies$ (c), also, F in Equation (4) is co-coercive with modulus 0.5 if T is nonexpansive. Moreover, F in Equation (4) is strictly (strongly) monotone if T is (strongly) contractive. So, contractive properties of T in the fixed point problem imply monotonicity ones in VI (1) and (4); see also Vasin and Ageev [29] and Berinde [28] for more details. However, by using the projection mapping $\pi_X(\cdot)$ onto X , we can make some reverse transformations. Take a number $\theta > 0$ and set $T(x) = \pi_X[x - \theta F(x)]$. Then VI (1) becomes equivalent to problem (3) or to the equation $G(x^*) = 0$ with $G(x) = x - \pi_X[x - \theta F(x)]$. However, this transformation can weaken monotonicity properties. In fact, if F is co-coercive with modulus $\mu > 0$, then G is co-coercive with modulus $\mu' = 1 - \theta/(4\mu)$ only if $\theta \in (0, 4\mu)$ [[22], Chapter 5].

Let us now consider the *optimization problem* of finding a point $x^* \in X$ such that $\varphi(x^*) \leq \varphi(x)$ for all $x \in X$, or briefly,

$$\min_{x \in X} \rightarrow \varphi(x), \quad (5)$$

and suppose for simplicity that $\varphi : \mathbb{R}^n \rightarrow \mathbb{R}$ is a differentiable function. Then Equation (5) implies VI (1), where $F(x) = \nabla \varphi(x)$, and the reverse implication holds if φ is (pseudo)convex. Note that the function φ is strongly convex (respectively, strictly convex, convex, pseudoconvex) if and only if its gradient map $\nabla \varphi$ is strongly monotone (respectively, strictly monotone, monotone, pseudomonotone) [22,24]. In this potential case, the mapping $F = \nabla \varphi$ possesses additional properties. For instance, if $\nabla \varphi$ is monotone and Lipschitz continuous, then it is co-coercive [22]. Moreover, the Jacobian $\nabla F(x) = \varphi''(x)$ must be symmetric.

Let us consider the *constrained l -person noncooperative game* with the common feasible set $X \subset \mathbb{R}^n$, where the i th player has a utility function $h_i : X \rightarrow \mathbb{R}$, which is concave in its i th variable u_i for $i = 1, \dots, m$, and $x = (u_1, \dots, u_l)^\top \in \mathbb{R}^n$. A point $x^* = (u_1^*, \dots, u_l^*)^\top \in X$ is said to be an equilibrium point for this game, if

$$h_i(u_{-i}^*, u_i) \leq h_i(x^*) \quad \forall (u_{-i}^*, u_i) \in X, i = 1, \dots, m.$$

Again suppose for simplicity that all the utility functions are differentiable. If we define

the mapping $F : X \rightarrow \mathbb{R}^n$ by

$$F_i(x) = -\frac{\partial h_i(u_{-i}, u_i)}{\partial u_i} \quad \text{for } i = 1, \dots, m; \quad (6)$$

then the equilibrium point problem becomes equivalent to VI (1) and (6) [30]. If additionally, X is the Cartesian product of the strategy sets, that is,

$$X = U_1 \times \dots \times U_l,$$

then the above concept is nothing but the known Nash equilibrium point [31]. Clearly, it reduces to a concave-convex saddle point problem if we also suppose that $l = 2$ and that the game is antagonistic, that is, $h_1(x) + h_2(x) = 0$, and involves in particular the Lagrangian saddle point problem in constrained convex optimization [6,10,11,22,32,33].

ALGORITHMS

Let us consider VI (1) where X is a nonempty, convex and closed set in $\mathbb{R}^n$ and $F : X \rightarrow \mathbb{R}^n$ is a continuous mapping. The linearization algorithms based on the sequential solution of auxiliary affine VIs constitute one of the most popular and investigated classes if F satisfies certain strengthened monotonicity properties. At the k th iteration of such an algorithm, given a point $x^k \in X$, the next iterate x^{k+1} is defined as a solution of VI: Find $\tilde{x} \in X$ such that

$$\langle F^k(\tilde{x}), x - \tilde{x} \rangle \geq 0 \quad \forall x \in X, \quad (7)$$

where $F^k(x) = F(x^k) + C_k(x - x^k)$, C_k is an $n \times n$ positive definite matrix. Different choices of C_k leads to various iterative methods. For instance, setting $C_k = \nabla F(x^k)$ gives the Newton method, setting $C_k = C$ with a symmetric and positive definite matrix C gives the (extended) projection method. Besides, one can take C_k as an approximation of $\nabla F(x^k)$, thus obtaining quasi-Newton methods. Concerning the convergence of the linearization algorithms we note that the Newton method attains the highest quadratic convergence rate, but requires rather restrictive assumptions for providing

global convergence [34, Corollary 2.6]. The simplest projection method corresponds to Equation (7) with $F^k(x) = F(x^k) + \lambda_k^{-1}(x - x^k)$, $\lambda_k > 0$ and is equivalent to the iterate

$$x^{k+1} = \pi_X[x^k - \lambda_k F(x^k)]. \quad (8)$$

It provides global convergence under co-coercivity of F and attains a linear convergence rate if F is strongly monotone and Lipschitz continuous, but requires knowledge of the corresponding constants for finding the stepsize λ_k .

In order to guarantee global convergence without *a priori* information, one can replace the initial VI by an optimization problem via introduction of some artificial *merit (gap) function*, which admits algorithms with linesearch procedures [10,11,13,35]. This approach is extended directly for more general mixed VIs and will be described in the section titled “Mixed Variational Inequalities”. However, the above methods fail to provide global convergence under only usual monotonicity conditions.

In order to essentially weaken convergence assumptions one can utilize suitable extrapolation procedures. The *extragradient method* [36] consists in replacing the usual projection iteration (8) with the double projection iteration

$$x^{k+1} = \pi_X(x^k - \beta_k F(y^k)), \quad y^k = \pi_X(x^k - \beta_k F(x^k)). \quad (9)$$

If F is a Lipschitz continuous mapping with modulus L , $X^* = X^d \neq \emptyset$, and $\beta_k = \beta \in (0, 1/L)$, then iterates in Equation (9) will converge to a solution of VI (1). In Khobotov [37], an implementable variant of the extragradient method, which finds the double stepsize β_k simultaneously was also proposed. Some other method to utilizing extrapolation is proposed in the so-called *combined relaxation (CR) methods* [38]. In this method, the auxiliary iteration (7) serves for computing parameters of a hyperplane separating, strictly, the current iterate x^k and the solution set X^* , whereas the main iteration consists in making the projections onto this hyperplane and onto the feasible set, if necessary. So, both the iterations

are different. We give now one of the CR algorithms [14,38].

Algorithm (CR). Choose a point $x^0 \in X$, numbers $\alpha \in (0, 1)$, $\beta \in (0, 1)$, $\gamma \in (0, 2)$. At the k th iteration, $k = 0, 1, \dots$, compute $\tilde{x}$ in Equation (7) and set $p^k = \tilde{x} - x^k$. If $p^k = 0$, stop. Otherwise determine m as the smallest nonnegative integer such that $\langle F(x^k + \beta^m p^k), p^k \rangle \leq \alpha \langle F(x^k), p^k \rangle$, set $y^k = x^k + \beta^m p^k$, $g^k = F(y^k)$, $\omega_k = \langle g^k, x^k - y^k \rangle$. If $g^k = 0$, stop. Otherwise set

$$x^{k+1} = \pi_X[x^k - \gamma(\omega_k / \|g^k\|^2)g^k].$$

These algorithms possess similar convergence properties, but do not require for L to be evaluated or even for F to be Lipschitz continuous. At the same time, the extrapolation methods attain a linear rate of convergence [14,39]. Similar methods can be found in Solodov and Tseng [40] and Sun [41]; see also Konnov [14,42] and Auslender [43].

Another approach consists in utilizing certain *regularization* techniques. For instance, the classical Tikhonov–Browder regularization [44,45] leads to the following auxiliary problem: Find $x^\varepsilon \in X$ such that

$$\langle F(x^\varepsilon) + \varepsilon x^\varepsilon, x - x^\varepsilon \rangle \geq 0 \quad \forall x \in X, \quad (10)$$

where $\varepsilon > 0$. In the case when F is monotone and continuous, and $X^* \neq \emptyset$, it is known [45,46] that each problem (10) has a unique solution and that the sequence of solutions $\{x^\varepsilon\}$ converges to the minimal norm solution x_n^* of VI (1) as $\varepsilon \rightarrow 0$, this property remaining valid in Banach spaces. Note also that the cost mapping $F^\varepsilon = F + \varepsilon I$ in Equation (10) is then strongly monotone. By utilizing suitable coercivity conditions one can maintain weakened convergence properties of regularization schemes in the nonmonotone case [47–51]. For instance, if the assumptions of Theorem 1 are fulfilled then each VI (10) has a solution, each sequence $\{x^{\varepsilon_k}\}$ has limit points, and if $\{\varepsilon_k\} \searrow 0$ all these limit points are solutions of VI (1) [51,52]. Some recent developments in this field can be found in Konnov [20] and Konnov and Dyabilkin [21].

The proximal point method [53,54] also consists in replacing the initial problem with

a sequence of perturbed auxiliary ones, but its regularization parameter may be in principle fixed. Given a point x^k , the next iterate is defined as a solution of VI: Find $x^{k+1} \in X$ such that

$$\langle F(x^{k+1}) + \lambda^{-1}(x^{k+1} - x^k), x - x^{k+1} \rangle \geq 0 \\ \forall x \in X,$$

with $\lambda > 0$. Again, if F is a monotone and $X^* \neq \emptyset$, the cost mapping above is strongly monotone and $\{x^k\}$ converges to a solution of VI (1). Moreover, its convergence can be established under certain generalized monotonicity conditions [55–58]. Although the auxiliary problems in regularization methods admit approximate solutions, they also may be rather expensive.

It should be noted that various constrained optimization methods are extended directly for VIs with nonlinear constraints, including exterior and interior penalty methods [59–63], dual Uzawa and multiplier type methods [22, 64–69], and hybrid schemes [10, 70, 71]. Besides, these methods are adjusted easily for GVI (12) with nonlinear constraints.

MIXED VARIATIONAL INEQUALITIES

Let X be again a nonempty, convex, and closed set in $\mathbb{R}^n$, $F: \mathbb{R}^n \rightarrow \mathbb{R}^n$ a continuous mapping, and $h: \mathbb{R}^n \rightarrow \mathbb{R}$ a convex continuous function. The mixed variational inequality problem (MVI) is the problem of finding a point $x^* \in X$ such that

$$\langle F(x^*), x - x^* \rangle + h(x) - h(x^*) \geq 0 \quad \forall x \in X. \quad (11)$$

Problem (11) was introduced in Lescarret [72] and Browder [73] and studied by many authors due to its various applications [3, 13, 14, 63]. In case $h \equiv 0$, it corresponds to the usual VI (1), whereas $F \equiv \mathbf{0}$ leads to the convex (nonsmooth) optimization problem

$$\min_{x \in X} h(x).$$

Besides, Equation (11) is equivalent to GVI (12) with the cost mapping $F + \partial h$, where

∂f denotes the subdifferential mapping of h . Nevertheless, peculiarities of MVI (11) enable one to investigate it via methods from the usual VIs. For instance, the assertions of Proposition 1 remain true for Equation (11).

By using some artificial gap (or merit) function, one can convert MVI (11) into an equivalent constrained optimization problem. The simplest regularized gap function is defined as follows:

$$\varphi_\lambda(x) = \max_{y \in X} \Phi_\lambda(x, y),$$

where $\lambda > 0$,

$$\Phi_\lambda(x, y) = \langle F(x), x - y \rangle - \|x - y\|^2 / (2\lambda) + h(x) - h(y).$$

Under the above assumptions, there exists the unique element $y_\lambda(x) \in X$ such that $\varphi_\lambda(x) = \Phi_\lambda(x, y_\lambda(x))$. It follows that $\varphi_\lambda(x) \geq 0$ for every $x \in X$, besides,

$$\varphi_\lambda(x) = 0 \text{ and } x \in X \iff x \in X^*,$$

where X^* denotes the solution set of MVI (11). Such functions for VIs were proposed in Auchmuty [74] and Fukushima [75] and extended for MVIs in Patriksson [76]. Note that the iterate $x^{k+1} = y_\lambda(x^k)$ corresponds to the forward–backward splitting method [77, 78], which clearly reduces to the projection method (8) if $h \equiv 0$ and has similar convergence properties. However, we can now utilize the descent approach with respect to φ_λ for selection of the stepsize.

Algorithm (DSE). Choose a point $x^0 \in X$ and a number $\lambda > 0$. At the k th iteration, $k = 0, 1, \dots$, we have a point $x^k \in X$, and set $p^k = y_\lambda(x^k) - x^k$. If $p^k = \mathbf{0}$, stop. Otherwise, find $\alpha_k \in [0, 1]$ such that $\varphi_\lambda(x^k + \alpha_k p^k) = \min_{\alpha \in [0, 1]} \varphi_\lambda(x^k + \alpha p^k)$, and set $x^{k+1} = x^k + \alpha_k p^k$.

Theorem 2 [13, Theorem 6.1; 76]. Suppose that F is continuously differentiable and strongly monotone on X . Then Algorithm (DSE) either terminates with a unique solution of MVI (11) or generates an infinite

sequence $\{x^k\}$, which converges to this unique solution.

A descent method with an Armijo type inexact linesearch procedure was proposed in Konnov [79]. Such methods can be based on different and more general gap functions [13,80]. They can utilize the Newton auxiliary problem instead of the projection step [13,81,82] and are adjusted for the case of nonlinear constraints [13,82,83]. One of the most interesting is the so-called D -gap function, which was proposed in Peng [84] for the usual VI when $h \equiv 0$. In Konnov [85], this gap function was applied for MVI (11). The D -gap function is defined as follows

$$\psi_{\lambda\mu}(x) = \varphi_\lambda(x) - \varphi_\mu(x),$$

where $0 < \mu < \lambda$. It follows that MVI (11) is equivalent to the unconstrained optimization problem

$$\min_{x \in \mathbb{R}^n} \rightarrow \psi_{\lambda\mu}(x).$$

Besides, it was shown in Konnov [85] that, unlike the usual gap functions, $\psi_{\lambda\mu}$ remains differentiable if F is so, regardless of the function h . Next, if $\nabla F(x)$ is positive definite on $\mathbb{R}^n$, then MVI (11) becomes equivalent to the equation:

$$\nabla \psi_{\lambda\mu}(x) = \mathbf{0},$$

which can be solved via efficient descent methods without computation of derivatives.

All the above descent methods require certain strengthened monotonicity of the mapping F . In the case when the mapping F is only monotone, but not strongly monotone, one can utilize several approaches to provide convergence. For instance, if the set X is bounded, the above descent methods can be inserted in a two-level parametric iterative scheme [13,86]. Next, they can be combined with either regularization or proximal point methods, with approximate solution of their auxiliary subproblems [80,87,88]. Some other way consists in applying the *(CR) methods* [89]; see also Konnov [14,80].

Algorithm (CRM). Choose a point $x^0 \in \mathbb{R}^n$, a sequence of functions $\psi_k : \mathbb{R}^n \rightarrow \mathbb{R}$ such

that ψ_k is differentiable and strongly convex with constant $\tau' > 0$, and its gradient ψ'_k is Lipschitz continuous with constant $\tau'' < \infty$. Choose numbers $\alpha \in (0, 1)$, $\beta \in (0, 1)$, $\gamma \in (0, 2)$. At the k th iteration, $k = 0, 1, \dots$, find m as the smallest nonnegative integer such that

$$\begin{aligned} & \langle F(x^k) - F(z^{k,m}), x^k - z^{k,m} \rangle \\ & \leq (1 - \alpha)\beta^{-m} \langle \psi'_k(z^{k,m}) - \psi'_k(x^k), z^{k,m} - x^k \rangle, \end{aligned}$$

where $z^{k,m}$ is a solution of the problem

$$\begin{aligned} \min_{y \in X} \rightarrow & \left\{ \langle F(x^k) - \beta^{-m} \psi'_k(x^k), y \rangle \right. \\ & \left. + \beta^{-m} \psi_k(y) + h(y) \right\}. \end{aligned}$$

Set $\theta_k = \beta^m$, $y^k = z^{k,m}$. If $y^k = x^k$, stop. Otherwise set $g^k = F(y^k) - F(x^k) - \theta_k^{-1}[\psi'_k(y^k) - \psi'_k(x^k)]$, $\omega_k = \langle g^k, x^k - y^k \rangle$, $x^{k+1} = x^k - \gamma(\omega_k / \|g^k\|^2)g^k$.

Note that we can simply choose $\psi_k(x) = 0.5\|x\|^2$, then computation of $z^{k,m}$ is again equivalent to the forward-backward splitting iteration with $\lambda = \beta^m$.

Theorem 3 [80, Theorem 6.1]. Suppose that F is monotone and $X^* \neq \emptyset$. Then Algorithm (CRM) either terminates with a solution of MVI (11) or generates an infinite sequence, which converges to a solution of MVI (11).

This CR method attains a linear rate of convergence if F is strongly monotone. For further development, see Konnov [90–92].

GENERALIZED VARIATIONAL INEQUALITIES

Now we turn to the multivalued extension of VI (1). This requires proper generalization of continuity type concepts. In what follows, $\Pi(S)$ denotes the family of all subsets of a set S .

Definition 3. [[14], Definition 2.1.1] Let X be a convex set in $\mathbb{R}^n$. A mapping $Q : X \rightarrow \Pi(\mathbb{R}^n)$ is said to be a K (Kakutani)-mapping if it is upper semicontinuous and has nonempty, convex, and compact values.

In this section we suppose that X is a nonempty, convex, and closed set in $\mathbb{R}^n$ and that $\mathbf{F}: X \rightarrow \Pi(\mathbb{R}^n)$ is a multivalued K -mapping. Then we can define the *generalized variational inequality problem* (GVI): Find an element $x^* \in X$ such that

$$\exists f^* \in \mathbf{F}(x^*), \langle f^*, x - x^* \rangle \geq 0 \quad \forall x \in X. \quad (12)$$

The necessity to investigate and solve such problems stems from the fact that many applied equilibrium-type models involve just multivalued mappings [8,14,16,24,42,51,93]. Together with GVI (12) we can define the *minimax dual problem* (DGVI): Find $x^* \in X$ such that

$$\forall f \in \mathbf{F}(x), \langle f, x - x^* \rangle \geq 0 \quad \forall x \in X; \quad (13)$$

compare Equation (2), which also seems to have appeared first in Debrunner and Flor [25]; see, for example, Konnov [14,12] for more details. We again denote by X^* (respectively, by X^d) the solution set of problem (12) (respectively, problem (13)). The basic existence and uniqueness results from the section titled “Theoretical Background” contained in Theorem 1 and Propositions 1 and 2 are transformed directly for GVI (12), after the proper adjustment of the monotonicity type concepts [12,14,16,51]. We also notice that the results described in the section titled “Algorithms” for the regularization and proximal point methods remain true in the multivalued case [14,22,46,51,54,58,71,94]. Note that these methods only replace the initial problem with a regularized one, but do not remove the basic difficulty to solve a multivalued GVI. At the same time, the streamlined extensions of some other solution methods described in the sections titled “Algorithms” and “Mixed Variational Inequalities”, such as descent and linearization ones may fail to provide convergence. For instance, the analog of the projection method (8) which is defined by

$$x^{k+1} = \pi_X[x^k - \lambda_k f^k], f^k \in \mathbf{F}(x^k),$$

again requires the strengthened monotonicity, but its stepsize λ_k must conform to the divergent series rule, which leads to

rather slow convergence; see, for example, Gol’shtein and Tret’yakov [22] and Konnov [12] for more details. It should be noted that the *averaging* [95,96] and *iterative regularization type methods* [97,46] provide convergence under the usual monotonicity, but require the same divergent series step size rule.

Besides, one can utilize *center type methods*, whose idea consists in sequential selection of the next iterate as an approximate center of a subset containing a solution combined with a proper reduction of this subset. The most known is the ellipsoid method, which was proposed first by Yudin and Nemirovskii [98] and Shor [99] for convex programming and afterwards adjusted for saddle point problems and VIs [100,101]. The analytic center methods and proximal level (or bundle) methods also follow this direction [102–106]. These methods usually include solution of rather difficult auxiliary problems at each iteration, but also enable one to weaken convergence assumptions.

We now turn to the *CR methods* for GVI (12) [14,107–109]. Suppose in addition that the feasible set X is defined by

$$X = \{x \in \mathbb{R}^n \mid h(x) \leq 0\}, \quad (14)$$

where $h: \mathbb{R}^n \rightarrow \mathbb{R}$ is a convex, but not necessarily differentiable function, and that the Slater constraint qualification is satisfied, that is, there exists a point $\tilde{x}$ such that $h(\tilde{x}) < 0$. Set

$$\mathbf{P}(x) = \begin{cases} \mathbf{F}(x) & \text{if } h(x) < 0, \\ \text{conv}\{\mathbf{F}(x) \cup \partial h(x)\} & \text{if } h(x) = 0, \\ \partial h(x) & \text{if } h(x) > 0. \end{cases}$$

One of suitable CR methods is then described as follows.

Algorithm (CRG). Choose a point $x^0 \in \mathbb{R}^n$, numbers $\alpha \in (0, 1)$, $\gamma \in (0, 2)$, and sequences $\{\lambda_l\} \searrow 0$ and $\{\eta_l\} \searrow 0$. Set $k = 0$, $l = 1$.

Step 1a: Choose q^0 from $\mathbf{P}(x^k)$, set $i = 0$, $p^i = q^i$.

Step 1b: If $\|p^i\| \leq \eta_l$, set $x^{k+1} = x^k$, $k = k + 1$, $l = l + 1$ and go to Step 1a.

Step 1c: Set $z^{i+1} = x^k - \lambda_i p^i / \|p^i\|$, choose $q^{i+1} \in \mathbf{P}(z^{i+1})$. If $\langle q^{i+1}, p^i \rangle > \theta \|p^i\|^2$, then set $y^k = z^{i+1}$, $g^k = q^{i+1}$, and go to Step 2. Otherwise, set $p^{i+1} = \pi_{\text{conv}\{p^i, q^{i+1}\}}(\mathbf{0})$, $i = i + 1$, and go to Step 1b.

Step 2: Set $\omega_k = \langle g^k, x^k - y^k \rangle$, $x^{k+1} = x^k - \gamma(\omega_k / \|g^k\|^2)g^k$, $k = k + 1$ and go to Step 1a.

It was shown in Konnov [107,108] (see also [[14], Sections 2.3 and 2.4]) that Algorithm (CRG) converges to a solution of GVIs (12) and (14) if $X^* = X^d \neq \emptyset$ and attains a linear rate of convergence (with respect to the index i) under certain additional assumptions.

VENDOR-MANAGED INVENTORY

MICHAEL J. FRY

Department of Quantitative Analysis
and Operations Management,
University of Cincinnati,
Cincinnati, Ohio

Vendor-managed inventory (VMI) refers to a supply chain agreement where an upstream agent, such as a supplier or manufacturer, takes control of the inventory management decisions for one or more downstream agents, such as retailers. For simplicity, we will refer to this upstream agent that gains decision making rights as the “supplier” and the downstream agents foregoing their decision making as “retailers.” Under VMI, the supplier makes decisions concerning the timing and quantity of deliveries of material to the retailer. In some cases, the supplier may also take ownership of these items even when they are located at the retailer—an arrangement known as *consignment*—but this is not required under VMI. VMI programs utilize information sharing between the retailer and the supplier in order to facilitate the matching of inventory with customer demand. In a typical system, retailers will periodically or continuously provide data to the supplier, which describes customer demand and current inventory levels. The supplier will then decide when and how much inventory to send to each retailer. In most cases, VMI programs will be subject to an initiating contract that specifies terms of the agreement including performance measures and payment terms.

VMI programs have been in existence for quite some time. One of the earliest large implementations of VMI occurred in the 1980s between Procter & Gamble and Wal-Mart. This VMI program has been widely praised as being successful in reducing costs for both the supplier (Procter & Gamble) and the retailer (Wal-Mart). Other examples of successful VMI implementations have been documented at Barilla SpA, Guinness Beer, and Campbell Soup Company in the

grocery industry as well as agreements in the electronics industry in companies such as Intel and Lexmark and between Boeing and Alcoa in heavy manufacturing. In general, VMI programs have been applied across a wide variety of industries and settings. There is ample evidence of supply chain savings linked to VMI programs, but savings are not guaranteed—particularly when one examines the individual agent costs in the supply chain.

The most common supply chain savings associated with VMI agreements are reductions in inventory levels and increased service levels. For instance, Buzzell and Ortmeyer [1] report sales increases of up to 25% and inventory turn increases of 30% in a VMI implementation in the retail clothing industry and discount merchandising. Parks [2] reports on a VMI program instituted by Procter & Gamble and its customers (retailers). The author finds that the retailers’ inventory turns were increased over 100%, service levels and retail sales increased while storage and handling costs were reduced. Burke [3] finds that a VMI agreement at GE Supply reduced receiving and stocking costs due to increased on-time arrival of product. Note that the benefits mentioned thus far apply almost exclusively to the retailers under VMI. Retailers in VMI programs also tend to realize an immediate savings in administrative costs as suppliers assume the burden of managing inventory. However, there can also be benefits for a supplier under VMI. Because VMI requires information sharing, the supplier often gains better visibility of customer demand. There may also be opportunities for reducing supplier costs through coordinating production and shipping activities. Finally, the use of VMI programs can encourage better retailer–supplier relations that can result in longer term contracts, more favorable payment terms, and increased customer loyalty.

However, VMI has not been shown to universally result in supply chain savings. Aichlmayr [4] reports that 3 out of 10 VMI

programs studied resulted in no benefits and another 3 provided modest benefits that were less than expected. Copacino [5] discusses VMI programs that led to the supplier paying higher transportation costs than without VMI because of increased shipping frequencies. Others claim that VMI simply allows retailers to transfer costs and risk to suppliers. Yao *et al.* [6] identify supply chain cost parameters that are more likely to lead to benefits from VMI, but they also find scenarios that can lead to increased costs and simply shifting the inventory downstream in the supply chain. Cachon and Fisher [7] examine a VMI program at Campbell Soup Company through a simulation study. Here, the authors find that information sharing without VMI could have provided the same benefits. Clark and Hammond [8] come to a similar conclusion in a separate empirical study that while VMI programs have produced benefits, simply sharing information between retailers and suppliers would produce similar savings.

VMI requires both extensive information sharing and close relations between suppliers and retailers. Many researchers have examined the benefits of information sharing in the absence of VMI (see *Information Sharing in Supply Chains*). There can also be derived benefits from the collaborative relationships required under VMI between retailers and suppliers. Such concepts are often promoted as part of category management programs or collaborative planning, forecasting, and replenishment (CPFR) initiatives. However, VMI programs go further than just the sharing of information and forming partnerships. VMI agreements also transfer decision making responsibilities from retailers to the supplier and may provide incentives to the supplier to make use of shared information that are not present under these other programs. VMI programs often alter the incentive structure for suppliers by linking their costs to retailer inventory performance. Thus, there is at least the opportunity for additional gains from VMI over information sharing alone.

In the remainder of this article we provide an overview of the current state of research on vendor-managed inventory. We will first

look at several of the purported benefits of VMI including shipment consolidation, and changes to individual agent incentives. Then we will discuss several challenges to VMI implementation including resistances to sharing information and technological difficulties. We provide an example of one type of analytical model for a VMI program and discuss related findings. Finally, we present conclusions and mention several open research questions related to VMI.

BENEFITS AND CHALLENGES OF VMI PROGRAMS

Benefits

Many of the reported benefits of VMI programs can be assigned to improved forecasting and better communication offered through information sharing. Here, we attempt to differentiate between those benefits that are more directly due to increased information sharing and those that are due to the transfer of decision rights in VMI programs. Lee *et al.* [9] and Disney and Towill [10] discuss the benefits of VMI from reducing information distortion and mitigating the bullwhip effect. Because VMI promotes information transparency and effectively reduces the number of agents making inventory-related decisions in the supply chain, we see less exacerbation of the bullwhip effect. The additional benefits from VMI on which we will focus are often due to improvements in transportation and production efficiencies or to changes in the incentives offered to individual supply chain agents under VMI.

VMI programs often offer opportunities for reducing delivery-related costs by consolidating shipments and creating more efficient delivery routes. It is well known that truckload (TL) shipping rates are considerably cheaper than less-than-truckload (LTL) rates. Thus, whenever a supplier can more fully utilize cube space in its vehicles, it can reduce delivery costs. Rather than reacting to delivery requests from retailers, VMI allows the supplier to anticipate upcoming orders and make multiple deliveries on the same route (Fig. 1). This can both improve cube utilization of the vehicles and reduce

Figure 1. Example of shipment consolidation under VMI.

the number of required vehicles for delivery. It also allows for more frequent deliveries to retailers, thus reducing lead times and required safety stock. From an operational perspective, VMI often forces the supplier to solve a vehicle routing problem (see the section titled “Vehicle Routing and Scheduling” in this encyclopedia) in addition to an inventory-allocation problem. While providing many opportunities for increased operational efficiency, the combined problem is often quite complex.

Several researchers have studied the improvements offered through improved shipping efficiency from VMI. Campbell *et al.* [11], Bertazzi *et al.* [12], Campbell and Savelsbergh [13], and Archetti *et al.* [14] study the inventory-routing problem in relation to VMI. The inventory-routing problem combines inventory decisions with route design; as such, it is an exceptionally difficult problem to solve to optimality. The focus in these papers is on the solution methods that often combine optimization models and heuristic search. Owing to the inherent intractability of the models, these inventory-routing problem formulations assume that demand is deterministic. Berman and Larson [15], Adelman [16], and Kleywegt *et al.* [17] extend the inventory-routing problem to stochastic demand scenarios. In these papers as well, the focus is on finding efficient

solution methods more so than identifying the savings offered by VMI programs. Nevertheless, VMI offers a clear potential for savings in improving the efficiency of the delivery process to multiple retailers using inventory-routing models. Extending these models to solve more practical scenarios is an open area for future research.

Cheung and Lee [18] consider a stochastic demand scenario and they focus on the ability of the supplier to consolidate shipments and rebalance inventory through VMI by postponing the assignment of inventory to specific retailers. Cheung and Lee conclude that both the supplier and retailers are better off under VMI because VMI reduces the amount of variability seen by the supplier due to pooling retailer orders; meanwhile, VMI provides increased reliability for replenishment to retailers. Çetinkaya and Lee [19] and Axsäter [20] also examine shipment consolidation under VMI for stochastic demand scenarios. Through a combination of analytical and numerical results, the authors find that VMI is beneficial in some situations (generally for fast-moving items), but not in others.

Fry *et al.* [21,22] examine VMI as a means of coordinating supplier production and retailer replenishment. Because suppliers (here considered to be manufacturers following a fixed production schedule) control both

the production and replenishment decisions, they can coordinate these decisions to reduce supply chain costs. The authors also provide an explicit model for the originating VMI contract where the supplier is penalized for having too much, or too little, inventory at the retailer. This type of VMI contract is found to be quite common in interviews of VMI-participating companies by Claassen *et al.* [23]. There are many papers that investigate contracts that attempt to realign incentives within the supply chain to overcome double marginalization and other inefficiencies inherent in decentralized systems. Double marginalization refers to the successive markups present in a vertical supply chain under simple wholesale price-only arrangements. Double marginalization leads to retailers typically understocking compared to the supply chain optimal inventory levels, thus leading to suboptimal supply chain performance. VMI programs provide an opportunity for reallocating decision rights and changing incentive structures to overcome such inefficiencies in decentralized supply chains.

Other researchers have examined incentive alignment contracts for VMI programs (see the section titled “Contracts in Supply Chains” in this encyclopedia). Cachon [24] models a multiple retailer VMI program where the penalty cost for not meeting customer demand is split between the supplier and the retailer. In Cachon’s model of VMI, the supplier sets all inventory reorder points. The author shows analytically that VMI will not coordinate the supply chain without fixed transfer payments between retailers and suppliers. Furthermore, a numerical study reveals that VMI will not provide any benefit in this scenario without fixed transfer payments. Nagarajan and Rajagopalan [25], Bichescu and Fry [26] also investigate the splitting of penalty costs, holding costs, or both, in VMI contracts. These researchers show that VMI can be beneficial for both parties in the agreement, but that it is dependent on the exact contract parameters chosen. Bernstein *et al.* [27] show that a simple pricing scheme under a VMI program can guarantee supply chain coordination in many scenarios, but that perfect coordination

may require consignment-type agreements in addition to VMI or pricing decisions that could run afoul of federal anticompetitive laws.

Challenges

There are many challenges to successful implementation of VMI programs. Two of the biggest challenges are (i) communication and technology requirements, and (ii) issues related to trust. VMI programs require regular communication between suppliers and retailers to transmit inventory and demand information. While some of the earliest VMI programs relied on periodic updates sent by fax or other means, most current VMI programs are supported by common information systems that either send the information automatically or allow all parties to view information in real time. Such information systems can be very costly and can often be difficult to implement and troubleshoot. However, the advancement of new technologies may ease the technological burdens of VMI programs. Electronic data interchange (EDI) standardizes many of the information exchanges between suppliers and retailers related to order placement, inventory updates, and so on. EDI standards have been in place for quite some time, but impediments to information sharing have remained.

Many enterprise resource planning (ERP) systems are now configured to support VMI programs. This makes it easier for suppliers and retailers to share information and often allows for real-time visibility of inventory and demand information throughout the supply chain. However, ERP systems still rely on large amounts of user input and errors are not uncommon. The evolving use of radio frequency identification (RFID) technology may reduce many of these user input errors and continue to enhance the ability to share information in the supply chain (see ***Inventory Inaccuracies in Supply Chains: How Can RFID Improve the Performance?***). However, RFID still suffers from technological challenges and high costs that have slowed its widespread adoption. While the aforementioned technologies may make it easier to implement and monitor VMI programs, they still involve considerable cost. These costs are

typically ignored in the academic literature that measure the benefits of VMI but in practice, they are nevertheless a real impediment to VMI programs.

VMI programs require very close relationships between the partners. The data required for operating a VMI program includes detailed demand information and inventory levels—data that are generally considered proprietary and a possible source of competitive advantage. Thus, any successful VMI program requires a large amount of trust between the partners that these data will not be shared with outside parties or otherwise exploited. Kumar [28] highlights the importance of trust in supply chain relationships. Kumar points to the VMI program between Wal-Mart and Procter & Gamble as an example of a successful supply chain relationship built on trust. As Kumar describes, VMI requires Wal-Mart to “share sales and price data and cede control of the order process and inventory management to P&G. P&G had to trust Wal-Mart enough to dedicate a large cross-functional team to the Wal-Mart account... and invest in a customized information link” [28, p. 102].

In passing control of the inventory replenishment process to the suppliers, retailers are placing a large amount of trust in believing that suppliers will not simply pass inventory directly to the retailer—a common complaint in some VMI programs. Chopra [29] reports that Seven-Eleven Japan Co. chooses to forego VMI program with its suppliers so that Seven-Eleven Japan can maintain complete control of its supply chain to support its overall strategy of providing frequent deliveries in small time windows to its stores. Of course, retailers do not simply rely on trust to prevent the adverse actions of suppliers. Many VMI agreements contain specific metrics and contractual terms that prevent the supplier from sending large amounts of inventory to retailers that do not sell. This is also a reason why VMI is often paired with consignment where the supplier retains ownership (and financial responsibility) for the inventory at the retailers. Because the supplier must continue to pay holding costs for items, this provides a disincentive for simply shipping inventory to the retailer that

may not sell. Verification and enforcement of VMI contract parameters can also present additional costs. While these costs are not usually included in the academic models of VMI, it is important to realize that they will reduce any savings garnered from VMI.

AN EXAMPLE OF A VENDOR-MANAGED INVENTORY MODEL

Consider a finite horizon, periodic review setting with a single retailer and a single supplier following a fixed production schedule. Customer demand is stochastic and i.i.d. We denote demand at the retailer by the random variable D and we assume that demand follows the distribution function $\Phi(\cdot)$ and density function $\phi(\cdot)$. Unfulfilled demand at the retailer is assumed to be backlogged. The supplier fills retailer orders using a combination of production and outsourcing so that the retailer always receives his full order amount.

Under a traditional supply chain structure where the retailer places orders and the supplier responds by filling those orders in full, the retailer will place orders using the well-known newsvendor order amounts (see **Supply Chain Coordination**). Let y^* denote this optimal order amount without VMI, where $y^* = \Phi^{-1}\left(\frac{p}{p+h_R}\right)$, p refers to the retailer's backlogging cost for not meeting demands and h_R is the retailer's per unit, per period holding cost.

Under VMI the retailer's inventory replenishment decision now passes to the supplier. The specific VMI program we will consider here is the same as that formulated in Fry *et al.* [21] where the retailer enforces upper and lower limits on the amount of inventory delivered by the supplier in each period. These limits are referred to as z and Z , respectively, for the minimum and maximum amounts of inventory allowed at the retailer after demand has been filled. We assume that there is a penalty amount of $b^+(b^-)$ incurred by the supplier for each unit of inventory at the retailer in violation of $Z(z)$. As previously mentioned, the supplier can replenish the retailer's inventory either from the on-hand

inventory or through outsourcing. Outsourcing results in a cost premium to the supplier of b_0 per unit.

Consider first the case where the supplier has no on-hand inventory ($x_S = 0$) and, thus, employs outsourcing. Let $V_n(x_R)$ be the supplier's expected cost-to-go of the optimal policy for replenishing the retailer from period n until the end of the horizon (period N) when the retailer has x_R units of inventory on-hand.

$$V_n(x_R) = -b_0 x_R + \min_{y \geq x_R} \left\{ b^- E[(z + D - y)^+] + b^+ E[(y - Z - D)^+] + b_0 y + E[V_{n+1}(y - D)] \right\} \quad (1)$$

$$\triangleq -b_0 x_R + \min_{y \geq x_R} J_n(y). \quad (2)$$

Under the assumption that $J_N(\cdot) = V_N(\cdot) = 0$, $J_n(\cdot)$ and $V_n(\cdot)$, $n = 1, \dots, N-1$ are convex and thus, a replenish up-to policy is optimal.

Next, consider the situation where the supplier does have inventory on-hand ($x_S > 0$). We know that as soon as the supplier exhausts her on-hand inventory, she will follow a replenish up-to policy until the end of the horizon, that is the next production opportunity, because of Equations (1) and (2). Let $K_n(y, x_E)$ be the expected cost-to-go from period n until the end of the horizon when the supplier has y units of inventory and let x_E be the echelon inventory, which is defined as the combined inventory at the supplier and the retailer (i.e., $x_E = x_S + x_R$).

$$K_n(y, x_E) = b^- E[(z + D - y)^+] + b^+ E[(y - Z - D)^+] - h_S y + h_S x_E + E[U_{n+1}(y - D, (x_E - D)^+)] \quad (3)$$

$$U_n(x_1, x_2) = \min_{x_1 \leq y \leq x_2} K_n(y, x_2) \quad (4)$$

A modification of the results found in Clark and Scarf [30] prove that these cost functions are also convex; thus, a replenish up-to policy is optimal when the supplier has inventory on hand as well. Define $\bar{y}$ as the optimal replenish up-to value when the

supplier has on-hand inventory and y_n^* as the optimal replenish up-to value when the supplier does not have on-hand inventory in period n . Clearly, it is optimal to replenish the retailer from on-hand inventory before outsourcing whenever possible. It is easily shown that the derivatives of the cost-to-go functions are identical for the nonoutsourcing and the general case. These two properties allow us to state the supplier's optimal replenishment policy under VMI as follows:

- if $x_S + x_R \geq \bar{y}$, replenish the retailer up-to $\bar{y}$;
- if $\bar{y} > x_S + x_R > y_n^*$, replenish the retailer up-to $x_S + x_R$;
- if $x_S + x_R \leq y_n^*$ in period n , replenish the retailer up-to y_n^* .

The optimal production values for the supplier under VMI can also be found. Let q be the combined amount of inventory at the supplier and the retailer at the beginning of the planning horizon (production cycle). We recursively define the supplier's cost $F(q)$ as

$$F(q) = h_S \left[\sum_{n=0}^{N-1} I_n \right] + b_0 \left[\sum_{n=1}^{N-1} O_n \right] + b^+ \left[\sum_{n=0}^{N-1} (I_n - Z)^+ \right] + b^- \left[\sum_{n=0}^{N-1} (z - I_n)^+ \right] \quad (5)$$

where

- I_n = inventory at the supplier, after delivery to the retailer, in period n ,
- D_n = demand experienced at retailer in period n ,
- O_n = amount outsourced in period n .

I_n and O_n are defined as

$$I_0 = \bar{x}_S + (q - \bar{x}_S - \bar{x}_R)^+ - (\bar{y} - \bar{x}_R)^+$$

where

$\bar{x}_S$ = inventory position at supplier just before production,

$\bar{x}_R$ = inventory position at retailer just before production,

$$I_n = [I_{n-1} - (\bar{y} - (y_{n-1} - D_{n-1}))^+]^+ \\ \text{for } n = 1, \dots, N-1,$$

$$O_n = [y_n^* - I_{n-1} - (y_{n-1} - D_{n-1})]^+ \\ \text{for } n = 1, \dots, N-1$$

$$y_0 = \bar{x}_R + (\bar{y} - \bar{x}_R)^+, \text{ and for } n = 1, \dots, N-1,$$

$$y_n = \begin{cases} y_{n-1} - D_{n-1} & : y_{n-1} - D_{n-1} \geq \bar{y} \\ \bar{y} & : y_{n-1} - D_{n-1} < \bar{y} \text{ and } I_n \geq y_{n-1} - D_{n-1} \\ I_n + O_n + y_{n-1} - D_{n-1} & : y_{n-1} - D_{n-1} < \bar{y} \text{ and } I_n < y_{n-1} - D_{n-1} \end{cases}$$

and $(x)^+ = \max(x, 0)$. Fry *et al.* [21] show that $F(q)$ is convex in q ; thus, a produce up-to policy is optimal.

Now consider a traditional, non-VMI setting where the retailer places orders and the supplier responds by filling orders from manufacturing and outsourcing, which we refer to as a retailer-managed inventory (RMI) scenario. We can write the equation for the cost under RMI of having q units in inventory at the supplier and the retailer at the beginning of the production cycle as

$$G(q) = h_S \left[\sum_{n=0}^{N-1} I_n \right] + b_0 \left[\sum_{n=1}^{N-1} O_n \right] \quad (6)$$

where the I_n values are exactly the same as under VMI in Equation (5), but

$$O_n = [y^* - I_{n-1} - (y^* - D_{n-1})]^+ \\ = [D_{n-1} - I_{n-1}]^+ \text{ for } n = 1, \dots, N-1.$$

where

y_n = retailer's inventory position just after being replenished by the supplier in period n ,

Here, $G(q)$ is also convex, so a produce up-to policy remains optimal.

Once the optimal replenishment and production policies are determined for both, the VMI and RMI scenarios, we can compare the performance of the different supply chain settings and evaluate the effectiveness of VMI under different contractual parameters. Figures 2 and 3 are adapted from results in Fry *et al.* [21]. Figure 2 compares many different possible VMI contracts to a traditional RMI scenario. Each point on a line represents a particular VMI contract with a given b^- and b^+ value. All other parameters remain fixed. This figure shows that VMI reduces supply chain costs under a variety of contractual parameters; however, supply chain savings are not guaranteed (see portion of figure where RMI outperforms VMI).

There are many contracts that result in supply chain savings that are not Pareto-improving, which means that either

Figure 2. Supply chain costs under VMI compared to RMI.

Figure 3. Individual agent costs under VMI.

the supplier or retailer would prefer the non-VMI scenario unless some sort of additional form of fixed transfer payment was instituted. Figure 3 demonstrates that individual retailer and supplier costs can be adjusted within a wide range by changing the VMI contractual parameters. Here, we adjust the range in which the supplier pays no penalties to the retailer for end-of-period inventory levels (i.e., $Q = Z - z$). All VMI contracts shown here result in supply chain savings compared to RMI, but the division of costs between supplier and retailer differ greatly under different contracts. Many of the individual agent costs shown here under VMI are greater than what the agent would pay under a traditional RMI scenario. Similar results requiring fixed transfer payments under VMI in many settings are found in Cachon [24] and Nagarajan and Rajagopalan [25]. Consistent with reports from industry, these researchers also find that when VMI does not perform well it is often the supplier that suffers.

CONCLUSIONS

The existing research demonstrates that VMI programs can be an effective means for improving supply chain efficiency and reducing system cost. VMI provides opportunities for improved supply chain visibility, shipment consolidation to reduce transportation costs, and aligning incentives between decentralized agents. Most of the existing research

papers can be divided between those that focus on the (i) transportation savings offered by VMI; and (ii) those that examine changes to the incentive structure for suppliers and retailers. Papers that examine transportation savings are often formulated in terms of the inventory-routing problem, and the focus has been on finding effective solution methods. Papers examining changes to the incentive structure under VMI generally examine the supply chain and individual agent savings offered by VMI, but typically ignore any savings offered from improved routing and shipment consolidation. Clearly there are still opportunities for more complex models that combine transportation savings with incentive contractual changes from VMI in the presence of stochastic demand.

In practice, the reports on VMI are mixed. Many implementations have led to considerable savings through increased service levels and reductions in holding costs. The existing models demonstrate that some of these failures from VMI may be due to improperly designed contracts that do not guarantee Pareto-improving solutions. Indeed, the results often show that finding Pareto-improving VMI agreements can often be difficult without the use of fixed transfer payments. Furthermore, the academic research tends to ignore many implementation and recurring costs under VMI including technology compatibility considerations as well as verification and enforcement issues. Recent work by Robinson [31] demonstrates that it

may be optimal for retailers to over-report customer demand levels under VMI. Current VMI models rely on perfect information visibility on the part of the supplier and truthful reporting by the retailer. However, such systems may not exist, and certainly are not costless; thus, further research into this area may be needed as well.

INTRODUCTION

There are numerous optimization problems of interest that are too difficult to solve to optimality in a reasonable amount of time. A practical remedy is to employ heuristics that can quickly compute good quality solutions. Neighborhood search algorithms, also called *local search algorithms*, are a wide class of heuristics that iteratively search for a better quality solution in a “neighborhood” of the current solution.

A critical issue in these methods is defining the neighborhood. As a rule of thumb, larger neighborhoods contain higher quality locally optimal solutions. However, larger neighborhoods typically require more time to search. A large neighborhood will not produce an effective heuristic unless one can search the large neighborhood efficiently. This section concentrates on neighborhood search algorithms where the size of the

neighborhood is “very large” with respect to the size of the input data and where the neighborhood can be implicitly searched in an efficient manner.

Preliminaries

We introduce several basic concepts used throughout this section. A *combinatorial optimization problem (COP)* is an optimization problem of the form: Minimize $\{f(S) : S \in \mathcal{F}\}$ where $\mathcal{F} \subseteq 2^E$ is a finite set of *feasible solutions*. In this context, $E = \{e_1, e_2, \dots, e_n\}$ is the *ground set*, $f : \mathcal{F} \rightarrow \mathbb{R}$ is the *objective function*, and 2^E denotes the set of all subsets of E . For example, in the traveling salesman problem (TSP), E corresponds to the edges in the graph, $\mathcal{F}$ corresponds to the set of feasible TSP tours, and $f(S)$ for $S \in \mathcal{F}$ corresponds to the length of the tour S . COPs can also be maximization problems. However, this section characterizes COPs as minimization problems without loss of generality as a notational convenience.

A *neighborhood function* $\mathcal{N}$ is a point-to-set map $\mathcal{N} : \mathcal{F} \rightarrow 2^{\mathcal{F}}$. Given a feasible solution $S \in \mathcal{F}$, the set $\mathcal{N}(S)$ is called the *neighborhood* of the solution S . The *size* of a neighborhood is the cardinality of the set $\mathcal{N}(S)$. An operation that modifies a solution S_i to obtain a solution $S_{i+1} \in \mathcal{N}(S_i)$ is called a *move*. If $f(S_{i+1}) < f(S_i)$, then the move is *improving*. A solution $S^* \in \mathcal{F}$ is *locally optimal* with respect to a neighborhood function $\mathcal{N}$ if and only if $f(S^*) \leq f(S)$ for all $S \in \mathcal{N}(S^*)$.

A *neighborhood search algorithm*, also called a *local search algorithm*, is an iterative algorithm that begins with a solution S_{i-1} at the *i*th *iteration*, and moves to an improving solution $S_i \in \mathcal{N}(S_{i-1})$ if one exists. Otherwise, the algorithm terminates with S_{i-1} . Algorithm 1 displays pseudocode for a generic neighborhood search algorithm. This pseudocode assumes the initial solution S_0 is input. The subroutine **BestNeighbor**($S_{i-1}, \mathcal{N}, f$) returns the best solution from the neighborhood $\mathcal{N}(S_{i-1})$ according to the objective function f .

Algorithm 1. Generic Neighborhood Search

S_0 // Initial solution
 $i \leftarrow 0$

repeat

$i \leftarrow i + 1$

$S_i \leftarrow \text{BestNeighbor}(S_{i-1}, \mathcal{N}, f)$

until $f(S_i) \geq f(S_{i-1})$

return S_{i-1}

A *very large-scale neighborhood* (VLSN) is a neighborhood that is “very large” in size with respect to the problem input. Typically, these neighborhoods are exponentially large, but this term is often used informally to describe neighborhoods that are too large to explicitly search in practice. Similarly, a *VLSN search algorithm* is a neighborhood search algorithm that searches a VLSN at each iteration. The phrase *VLSN search* was originally coined by Ahuja *et al.* [1].

Although the focus is on VLSN search algorithms for NP-hard COPs, we discuss how the simplex method can be viewed as a neighborhood search algorithm to illustrate how VLSN search relates to regular neighborhood search. During the simplex method, a basic feasible solution is represented by partitioning the decision variables into a set of basic variables B and a set of nonbasic variables N . A move, which is called a *pivot* in simplex terminology, exchanges one decision variable from B with a decision variable from N . The neighborhood of a basic feasible solution is the set of all basic feasible solutions that may be constructed from it with a single move. Analogously, a simplex-based VLSN search method is column generation. In column generation, the set of decision variables is too large to be represented explicitly so the nonbasic variables are implicitly searched to determine the entering basic variable. More detailed descriptions of the simplex method and column generation can be found in Bertsimas and Tsitsiklis [2].

Previous surveys of VLSN search techniques can be found in Ahuja *et al.* [1,3] and in Altner *et al.* [4]. A survey of large

neighborhood search techniques specifically for the TSP can be found in Deineko and Woeginger [5].

Variable-Depth Neighborhood Search Algorithms

Neighborhoods based on exchanging two or three elements simultaneously can often be explicitly searched in a reasonable amount of time. Exchanging a larger number of elements may lead to neighborhoods containing better local optimal solutions, but such neighborhoods typically cannot be searched efficiently. Variable-depth search algorithms are local search algorithms that (in principle) consider neighborhoods where a variable number of elements can be exchanged; to make the search practical, heuristics are used to search the neighborhood. There are variable-depth search algorithms for a large number of applications that obtain nearly optimal solutions efficiently. Such algorithms are the focus of this section.

Let S_i and S_{i+1} be solutions of a COP with ground set E . The move from solution S_i to solution S_{i+1} is a *k-exchange* if $|S_i \setminus S_{i+1}| = |S_{i+1} \setminus S_i| = k$ for a positive integer k . A neighborhood where $|S_i \setminus S_{i+1}| = |S_{i+1} \setminus S_i| \leq k$ for all $S_{i+1} \in \mathcal{N}(S_i)$ is a *k-exchange neighborhood* of S_i . A *k-exchange neighborhood* is said to have *depth k*.

A *variable-depth neighborhood search algorithm* begins with a solution S_{i-1} at the i th iteration, and moves to an improving solution S_i in the $|E|$ -exchange neighborhood of S_{i-1} if an improving move can be identified. Otherwise, the algorithm terminates with S_{i-1} . At each iteration, a variable-depth neighborhood search algorithm typically only partially explores the *k-exchange neighborhood* for each $k \in \{1, 2, \dots, |E|\}$, thus avoiding the $\Omega(|E|^k)$ lower bound of explicitly searching the entire neighborhood.

We now illustrate an example of a variable-depth neighborhood search algorithm on the maximum cut problem (MAX CUT). MAX CUT is defined as follows: Given an undirected graph $G = (V, A)$ where each edge $e \in A$ has weight w_e , partition the vertices V into two subsets X and Y to maximize the sum of the weights of the edges in the cut

$(X, Y) = \{(i, j) : i \in X \text{ and } j \in Y\}$. Let $f(X, Y)$ denote the sum of the weights in (X, Y) .

Pseudocode for a generic variable-depth search algorithm for MAX CUT is presented in Algorithm 2. Algorithm 2 takes an initial solution S_0 as input. The i th iteration of the algorithm starts with a solution S_{i-1} and either moves to a new solution S_i where $f(S_i) > f(S_{i-1})$ or maintains the solution S_{i-1} if no better solution is discovered. Within each iteration of the variable-depth search, there are $|V|$ **rounds**. M_j denotes the set of vertices that may not be moved during round $j + 1$, and (X_j, Y_j) denotes the cut constructed during round j .

The subroutine $\text{flip}(X_{j-1}, Y_{j-1}, v)$ returns a new cut (X_j, Y_j) , where vertex v has been moved from the subset containing it to the other subset. For example, if $v \in X_{j-1}$, then $\text{flip}(X_{j-1}, Y_{j-1}, v)$ returns a cut where $X_j = X_{j-1} \setminus v$, and $Y_j = Y_{j-1} \cup \{v\}$.

Algorithm 2. Generic Variable-Depth Search for MAX CUT

```

 $S_0$  // Initial solution
 $i \leftarrow 0$ 

repeat
     $i \leftarrow i + 1$ 
     $M_0 \leftarrow \emptyset$ 
     $(X_0, Y_0) \leftarrow S_{i-1}$ 

    for  $j = 1$  to  $|V|$  do
         $v_j^* \leftarrow \text{argmax}_{v \in V \setminus M_{j-1}} \{f(\text{flip}(X_{j-1}, Y_{j-1}, v))\}$ 

         $M_j \leftarrow M_{j-1} \cup \{v_j^*\}$ 

         $(X_j, Y_j) \leftarrow \text{flip}(X_{j-1}, Y_{j-1}, v_j^*)$ 
    end for

     $S_i \leftarrow \{(X_k, Y_k) : k = \text{argmax}_{j \in \{1, \dots, |V|\}} f(X_j, Y_j)\}$ 

until  $f(S_i) \leq f(S_{i-1})$ 
return  $S_{i-1}$ 
    
```

A special type of variable-depth neighborhood search algorithm is called an *ejection chain*. Loosely defined, an *ejection chain* is a variable-depth neighborhood search algorithm that iteratively generates a structured alternating sequence of additions and deletions $S_1, S_2, \dots, S_k$ where

1. $|S_1| = |S_j|$ for all odd values of j , and
2. $|S_2| = |S_j|$ for all even values of j .

Ejections chains were first introduced by Glover [6] for solving the TSP. Glover originally developed ejection chains by extending and generalizing the ideas of Lin and Kernighan [7]. Many variable-depth neighborhood search algorithms, particularly those for vehicle routing problems (VRPs), rely on ejection chains at each iteration in order to search the neighborhood.

Problem-specific variable-depth and ejection-chain-based algorithms have been successfully used for quickly computing good quality solutions to a wide variety of difficult COPs. Gamboa *et al.* [8], Glover [6], Johnson and McGeoch [9], Lin and Kernighan [7], Mak and Morton [10], Pesch and Glover [11], Rego [12], and Zachariasen and Dam [13] consider such algorithms for the TSP. The Lin–Kernighan search was the first variable-depth neighborhood search algorithm for the TSP and is still considered the best general framework for variable-depth neighborhood search algorithms for the TSP. At the time of this publication, Helsgaun’s [14] implementation of the Lin–Kernighan search for the TSP is often considered the fastest such neighborhood search algorithm and has successfully obtained optimal solutions for all instances in TSPLIB for which optimal solutions are known and verified.

Variable-depth neighborhood search algorithms are also commonly used for VRPs. Rego [12] describes a subpath ejection chain method for a VRP with vehicle capacities and route length restrictions. Xu and Kelly [15] extended the work of Glover [6] to solve a VRP with vehicle capacities using an ejection chain method. Rego and Roucairol [16] study a parallel tabu search algorithm using ejection chains for a standard VRP. Sontrop *et al.* [17] present an ejection chain method for a VRP with time window constraints.

There are numerous other difficult COPs that have been approached with variable-depth neighborhood search algorithms. Dorndorf and Pesch [18] apply ejection chain techniques to a series of benchmark instances in the clustering literature and obtain excellent results. Yagiura *et al.*

[19,20] consider variable-depth heuristics for the generalized assignment problem, which is the problem of finding a minimum-cost assignment of jobs to agents subject to one or more additional linear constraints. In the more recent study, Yagiura *et al.* [19] obtained solutions that deviated from the best previously reported solutions for benchmark instances from the OR-Library by 0.16% at most.

Variable-depth neighborhood search algorithms have also been applied to a bottleneck assignment problem [21], nurse scheduling [22], parallel machine scheduling [23], uniform graph partitioning [24,25], and very-large-scale integration (VLSI) circuit design [26]. Kernighan and Lin's paper on uniform graph partitioning [25] is the first published work on variable-depth neighborhood search.

Cyclic Exchange Neighborhood Search Algorithms

The cyclic exchange neighborhood was developed for solving minimum-cost partitioning problems. Let $S = \{S_1, S_2, \dots, S_K\}$ be a partition of a ground set E . Roughly speaking, a move in a cyclic exchange neighborhood permits one element to be transferred from subset S_i into subset S_j , which in turn causes another element to be transferred from subset S_j into subset S_k . This chain of transfers continues until an element is transferred into S_i and thus completes a cycle. In this section, we discuss cyclic exchange neighborhoods and reference applications to a wide range of settings.

More formally, let E be the ground set for a COP. The collection of subsets $\{S_1, S_2, \dots, S_K\}$ is a K -partition of E if no subset is empty, the sets are pairwise disjoint, and the union of the sets is E . A *partitioning problem* is a COP where the objective is to find a partition $T = \{T_1, T_2, \dots, T_K\}$ of E that minimizes $\sum_{j=1}^K c(T_j)$, where $c(T_j)$ is the cost of subset $T_j \subseteq E$.

Let $S = \{S_1, S_2, \dots, S_K\}$ and $T = \{T_1, T_2, \dots, T_K\}$ be two K -partitions of E . We say that T is a *1-neighbor* of S if $|T_j \setminus S_j| \leq 1$ and $|S_j \setminus T_j| \leq 1$ for all $j \in \{1, 2, \dots, K\}$. If T is a 1-neighbor of S , then T can be obtained from S via a *1-transfer*. Being a 1-neighbor is

symmetric: if T is a 1-neighbor of S , then S is a 1-neighbor of T .

Suppose $S = \{S_1, S_2, \dots, S_K\}$ is a K -partition and $T = \{T_1, T_2, \dots, T_K\}$ is obtained from S via a 1-transfer. From S and T , we can construct the (S, T) -transfer graph as follows: For each element in the ground set E , there is a corresponding vertex in the (S, T) -transfer graph. For each $k \in \{1, 2, \dots, K\}$, if T_k is obtained from S_k by inserting element i and deleting element j [that is, $T_k = (S_k \setminus i) \cup \{j\}$], then (i, j) is an edge of the (S, T) -transfer graph. Note the (S, T) -transfer graph is a disjoint union of cycles and paths because each vertex of the graph has at most one incoming edge and at most one outgoing edge.

If the (S, T) -transfer graph consists of a single cycle, we say T can be obtained from S via a *cyclic exchange*. Specifically, if the cycle is $i_1, \dots, i_k, i_1$, then T is obtained from S as follows: for each $j = 1$ to k , one inserts i_j into the subset of S containing i_{j+1} and then deletes i_{j+1} from that subset. (Here, i_{k+1} is equivalent to i_1 .) Similarly, if the (S, T) -transfer graph consists of a single path, we say T can be obtained from S via a *path exchange*. The *cyclic exchange neighborhood* (or, *path exchange neighborhood*) of a K -partition S consists of all K -partitions that may be obtained from S by a single cyclic (or, path) exchange.

Figure 1 illustrates a cyclic exchange. Here, vertex e_1 will be transferred from subset T_1 to subset T_2 . Vertex e_4 will be transferred from subset T_2 to subset T_4 . Vertex e_{10} will be transferred from subset T_4 to T_5 . Finally, the cyclic exchange will be completed by transferring vertex e_{13} from subset T_5 to subset T_1 .

To find an improving cyclic exchange starting with a given K -partition $S = \{S_1, S_2, \dots, S_K\}$ we create a new graph called the *improvement graph*. For each element in the ground set E , there is a corresponding vertex in the improvement graph. For every pair i, j of elements of E that are in different subsets of the partition S , there is an edge (i, j) in the improvement graph. Suppose S_k is the part of the K -partition S that contains element j . Then the edge (i, j) is interpreted as a transfer of element i into S_k and a transfer of a different element j out of S_k .

Figure 1. Illustration of a generic cyclic exchange.

Let $S'_k = (S_k \setminus \{j\}) \cup \{i\}$ be the updated subset if the cyclic exchange is executed. The cost of the edge (i, j) in the improvement graph is $c_{ij} = c(S'_k) - c(S_k)$, which is the net change in cost from transferring element i into S_k and transferring element j out.

A cycle $C = i_1, \dots, i_k, i_1$ in the improvement graph is *subset-disjoint* with respect to a K -partition S if no two elements of C belong to the same subset in S . In order for the total weight of a cycle in the improvement graph to accurately reflect the change in the objective function from a cyclic exchange, the cycle must be subset-disjoint.

Finding a minimum cost subset-disjoint cycle is NP-complete [27] but it is one of those NP-complete problems that is relatively easy to solve in practice. Thus, heuristics are used to search the improvement graph in order to construct improving cyclic exchanges. Effective heuristics for constructing negative cost subset-disjoint cycles are presented in Refs 28 and 29.

The improvement graphs and the transfer graphs are closely related. Suppose C is a subset-disjoint cycle in the improvement graph for partition S , and T is the partition obtained by performing the cyclic exchange induced by C . Then the (S, T) -transfer graph consists of the cycle C .

In addition, cyclic exchanges and subset-disjoint cycles in the improvement graph are closely related. Suppose S is a K -partition, and let G be the resulting improvement graph. There is a one-to-one correspondence between cyclic exchanges from S and subset-disjoint directed cycles in G . Moreover, the cost of a subset-disjoint cycle C is the net

change in objective value by performing the induced cyclic transfer.

There are several tricks to improving the running time of a cyclic exchange neighborhood search routine. For example, in practice, it is often much faster to update an improvement graph using the improvement graph from the previous iteration rather than constructing a new improvement graph from scratch. In addition, a path exchange may be transformed into a cyclic exchange by adding dummy vertices. This allows one to use a single search algorithm to identify both improving cyclic exchanges and improving path exchanges.

The size of the cyclic exchange neighborhood is a function of the number of partitions and the number of elements in the ground set. For K -partitions of n elements, the cyclic exchange neighborhood is of size $O(n^K)$. When K is permitted to grow with n , the size of the neighborhood is typically exponential.

Cyclic exchange neighborhoods have been successfully applied to a diverse selection of COPs. Thompson and Orlin [27] originally introduced the cyclic exchange neighborhood and the idea of VLSN search in general. Although, Thompson and Orlin limit their study to the VRP, their methods naturally generalize to other partitioning COPs. Thompson and Psaraftis [28] was the first published discussion of a cyclic exchange neighborhood search algorithm. Although they focused on the VRP, they demonstrated the potential usefulness of cyclic exchange neighborhoods for solving a wide range of partitioning problems. Agarwal *et al.* [30] extended the approach of Thompson and Psaraftis by allowing a set of consecutive cities in a vehicle tour to be transferred from one subset of a partition to another. The algorithm of Agarwal *et al.* obtained solutions within 1% of the best previously reported objective value on a series of benchmark instances that are now contained in the OR-Library. Sindhuchao *et al.* [31] applied similar ideas to an inventory routing problem.

Cyclic exchange neighborhoods have also been used in a variety of scheduling problems. Frangioni *et al.* [32] apply these ideas to

a parallel machine-scheduling problem with the objective of minimizing the makespan and showing that their algorithm outperforms other benchmark heuristics on several classes of randomly generated instances using standard instance generators. Abdullah *et al.* [33,34] designed a cyclic exchange neighborhood search algorithm for university examination timetabling and subsequently built upon this algorithm by adding tabu lists. The algorithm described in the latter paper obtains the best known results on a set of benchmark instances.

Cyclic exchange neighborhoods have also been used in a wide variety of assignment problems. Ahuja *et al.* [35] designed a VLSN search method to compute a minimum-cost fleet assignment of planes to flight legs while satisfying a variety of constraints. Ahuja *et al.* [36] generalize this approach to airline fleet assignment problems that incorporate time window constraints. Ahuja *et al.* [37] adapt a cyclic exchange neighborhood for the quadratic assignment problem (QAP). This is particularly interesting since the QAP is not a partitioning problem, which means that a cyclic exchange neighborhood is not directly applicable. Nevertheless, Ahuja *et al.* show their approach consistently produces better solutions in less time than leading two-exchange neighborhood search algorithms.

In addition to the above, Yagiura *et al.* [38] introduced a cyclic exchange neighborhood for a *multiresource generalized assignment problem* (MRGAP). Unlike most cyclic exchange neighborhood search algorithms, Yagiura *et al.* relaxed the condition that the cycles must be subset-disjoint, citing that the cost of any cycle in their improvement graph serves as a reasonably good approximation for the cost of the actual exchange. Mitrović-Minić and Punnen [39] expand VLSN research on MRGAP by combining concepts from cyclic exchange neighborhood search and the variable neighborhood search technique of Mladenović and Hansen [40]. Mitrović-Minić and Punnen also discuss how their very large-scale variable neighborhood search technique can be extended to other difficult COPs.

Other assignment problems that have been effectively solved using cyclic exchange

neighborhood search algorithms include a problem of assigning weapons to targets to minimize the survivability of all possible targets [41] and a distribution network design problem involving location, fleet assignment, and routing decisions that arises in the trucking industry [42].

Cyclic exchange neighborhoods have been used in numerous other settings. Ahuja *et al.* [29,43] introduce cyclic exchange neighborhood search algorithms for the capacitated minimum spanning tree problem (CMST). CMST is a minimum spanning tree problem subject to the constraint that if the root and its incident edges were deleted from the spanning tree, then each component has at most K vertices, where K is part of the problem input. Ahuja *et al.* [44] designed a cyclic exchange neighborhood for a multi-period production planning problem that involves constraints on production capabilities, inventory space and the perishability of products. Ahuja *et al.* [45] developed a cyclic exchange algorithm for a capacitated facility location problem with single-source constraints. Cunha and Ahuja [46] designed several cyclic exchange neighborhood search algorithms for the K -constrained multiple knapsack problem (K-MKP). K-MKP is a generalization of the knapsack problem, where each item has K types of weights and each knapsack has K types of capacity. Kulkarni and Fathi [47] develop a cyclic exchange neighborhood search algorithm for the q -Mode Problem, which is a problem that arises in cluster analysis. Magazine *et al.* [48] produced a cyclic exchange neighborhood for a problem that arises in the design of printed circuit boards. Nemani *et al.* [49] employ a cyclic exchange neighborhood search algorithm for an intermodal load planning problem, where the objective is to load containers from cargo ships and from trucks onto intermodal trains in a fashion that minimizes the transfer costs and rail car usage while ensuring all containers are arranged to limit air resistance. Finally, Scaparra *et al.* [50] created a cyclic exchange algorithm for the Capacitated Vertex p -Center Problem. The Capacitated Vertex p -Center Problem consists of locating p facilities and assigning clients to them to

minimize the maximum distance between a client and its assigned facility while not exceeding any facility's capacity for servicing clients.

The idea of finding improved solutions by determining negative cost cycles in improvement graphs has been used in several other contexts. For example, Talluri [51] identified cost-saving exchanges of equipment type between flight legs for a daily airline fleet assignment problem by finding negative cost cycles in a related network. In addition, Schneur and Orlin [52] solved a linear multicommodity flow problem by iteratively detecting and sending flow around negative cost cycles. Their technique readily extends to a cycle-based improvement heuristic for the integer multicommodity flow problem.

Other Very Large-Scale Neighborhood Search Algorithms

In designing VLSN search algorithms, researchers have drawn inspiration and techniques from more than 50 years of algorithmic development in mathematical programming and computer science. In this section, we describe a diverse collection of approaches for developing VLSN search algorithms.

One approach for developing VLSNs is to base them on combining several independent moves. compounded independent move (CIM) neighborhoods are neighborhoods based on simultaneously executing two or more moves whose effects on the objective value are independent of one another; that is, the change in the objective value due to the compound move is equivalent to the sum of the changes due to the individual moves. CIM neighborhoods were designed by Congram *et al.* [53] for a machine-scheduling problem and by Potts and van de Velde [54] for the TSP. Their techniques searched a CIM neighborhood with dynamic programming. Potts and van de Velde referred to the general idea of searching a CIM neighborhood with dynamic programming as *dynasearch*.

There are several other examples of CIM neighborhoods. Ergun *et al.* [55] and Gendreau *et al.* [56] searched CIM neighborhoods to solve VRPs. Taillard [57] used CIM neighborhoods for solving clustering problems.

Dror and Levy [58] used CIM neighborhoods for solving the inventory routing problem (IRP). The IRP combines inventory management and vehicle routing into one resource allocation problem. Brueggemann *et al.* [59] implemented a CIM neighborhood for a minimum makespan parallel machine scheduling problem where the neighborhood is searched by solving a bottleneck assignment problem. Bottleneck assignment problems are a variant of assignment problems where the objective is to choose an assignment $\mathcal{M}$ to minimize $\max\{c_e : e \in \mathcal{M}\}$ where c_e is the cost of edge e . Öncan *et al.* [60] discussed the more general problem of designing VLSN search algorithms for partitioning problems in general using a CIM neighborhood that is searched by solving a matching problem.

There are also other examples of dynasearch being used in different contexts. Ergun and Orlin [61] use dynasearch to search a VLSN for the TSP. Ergun and Orlin [62] and Grosso *et al.* [63] use dynasearch for solving single-machine total-weighted tardiness scheduling problems.

VLSNs can also be searched by solving a mathematical program. Suppose x is a solution to a mathematical program. For a given subset I of indices, we say that another feasible solution y is I -adjacent to x if $y_i = x_i$ for $i \in I$, and we say y is in the I -neighborhood of x . I -neighborhoods are conveniently searched using mathematical programming software. Davenport *et al.* [64] and Pesant and Gendreau [65] design large neighborhoods that are searched using constraint programming. In addition, Danna *et al.* [66] have proposed a method called *relaxation-induced neighborhood search (RINS)*, which uses a linear programming solution to construct a neighborhood and solves an integer program to search the neighborhood. The RINS heuristic of Danna *et al.* has been implemented in the CPLEX 9.0 MIP solver.

VLSNs can also be based on polynomially solvable special cases of NP-hard COPs. Researchers have developed a substantial literature on such cases, which often lend themselves to VLSNs that can be searched in polynomial time. For example, Carlier and Villon [67] presented a polynomial-time algorithm for finding an optimal *pyramidal tour*

for the TSP. A pyramidal tour is a sequence $i_1, \dots, i_n$ such that for some value k , the indices in the subsequence $i_1, \dots, i_k$ are in increasing order, and the indices in the subsequence $i_k, \dots, i_n$ are in decreasing order. For a given tour T , its pyramidal neighborhood is the set of pyramidal tours that would result if one first relabeled the vertices (or cities) so that $T = 1, \dots, n$. Therefore, any algorithm for finding a minimum-cost pyramidal tour can be used for finding a minimum-cost pyramidal neighbor.

As another example of this practice, for a given fixed value K and an initial ordering of cities, there is a polynomial-time dynamic program for finding an optimal tour subject to the constraint that city i precedes city j if and only if $j \geq i + K$. Simonetti and Balas [68] use this algorithm as the basis for developing a VLSN search algorithm.

VLSNs can also be constructed by exploiting the physical geography of the underlying COP. For example, Ahuja *et al.* [69] did this for a railroad blocking problem. Blocking problems, which also arise in parcel delivery, trucking, and air transportation, model how to consolidate a large number of shipments into *blocks* to reduce the total handling costs. The VLSN search algorithm devised by Ahuja *et al.* iteratively improves a blocking plan by defining a neighborhood within a single railroad yard to consider reclassifying all freight currently in the yard into different blocks.

Lastly, a unique result is that certain VLSNs can be generated using context-free grammars (CFGs). Bompadre and Orlin [70] showed how to use CFGs to generate exponentially large neighborhoods for sequencing problems. Moreover, for some sequencing problems such as the TSP and the linear ordering problem, they developed an algorithm that takes the grammar and the problem data as input and then finds the minimum-cost neighbor in polynomial time. In addition to presenting an innovative use of CFGs, this paper demonstrates how a single algorithm can be used to search a wide range of different exponentially sized neighborhoods. Mouthuy *et al.* [71] briefly overview how they used this CFG technique to generate neighborhoods to implement VLSNs for the TSP in Comet [72], an

object-oriented programming language for constraint-based local search.

WARDROP EQUILIBRIA

JOSÉ R. CORREA

Industrial Engineering Department,
Universidad de Chile, Santiago, Chile

NICOLÁS E. STIER-MOSES

Graduate School of Business, Columbia
University, New York, New York

A common behavioral assumption in the study of transportation and telecommunication networks is that travelers or packets, respectively, choose routes that they perceive as being the shortest under the prevailing traffic conditions [1]. The situation resulting from these individual decisions is one in which drivers cannot reduce their journey times by unilaterally choosing another route, which prompted Knight [2] to call the resulting traffic pattern an equilibrium. Nowadays, it is indeed known as the *Wardrop (or user) equilibrium* [3], and it is effectively thought of as a steady state evolving after a transient phase in which travelers successively adjust their route choices until a situation with stable route travel costs and route flows has been reached [4]. In a seminal contribution, Wardrop [5, p. 345] stated two principles that formalize this notion of equilibrium and the alternative postulate of the minimization of the total travel costs. His first principle reads:

The journey times on all the routes actually used are equal, and less than those which would be experienced by a single vehicle on any unused route.

Wardrop's first principle of route choice, which is identical to the notion postulated by Kohl [1] and Knight [2], became accepted as a sound and simple behavioral principle to describe the spreading of trips over alternate routes due to congested conditions [6].

Since its introduction in the context of transportation networks in 1952 and its mathematical formalization by Beckmann

et al. [7], transportation planners have been using Wardrop equilibrium models to predict commuters decisions in real-life networks [6,8]. These models have been and are still used today to evaluate alternative future scenarios and decide a route of actions. Typical examples include allocation of investment for capacity expansion when building roads and bridges, optimizing the value of tolls, and making policy decisions. The work of Korolis *et al.* [9] introduced these concepts in telecommunication research, which have become popular ever since [10].

THE BASIC MODEL

An instance of the *traffic assignment problem* is given by the transportation offer—represented by the network topology, road geometry, road capacity, and arc link travel cost functions—and the transportation demand—represented by the list of origin–destination (OD) pairs and their demand rates.

We consider a directed network $\mathcal{G} = (\mathcal{N}, \mathcal{A})$, and a set $\mathcal{C} \subseteq \mathcal{N} \times \mathcal{N}$ of commodities represented by OD pairs. For each $k \in \mathcal{C}$, a flow of demand rate equal to d_k must be routed from the corresponding origin to its destination. The basic model assumes that demands are arbitrarily divisible; in fact, the routing decision of a single individual has only an infinitesimal impact on other users. For $k \in \mathcal{C}$, let $\mathcal{R}_k$ be the set of routes in $\mathcal{G}$ connecting the corresponding origin and destination, and let $\mathcal{R} := \bigcup_{k \in \mathcal{C}} \mathcal{R}_k$. A link flow is a nonnegative vector $f = (f_a)_{a \in \mathcal{A}}$ describing the traffic rate in each link. Furthermore, a nonnegative, nondecreasing, and continuous link travel cost function $t_a(\cdot)$, with values in $\mathbb{R}_{\geq 0} \cup \{\infty\}$, maps the flow f_a on arc a to the time needed to traverse a . A route flow is a nonnegative vector $h = (h_r)_{r \in \mathcal{R}}$ that meets the demand, that is, $\sum_{r \in \mathcal{R}_k} h_r = d_k$ for $k \in \mathcal{C}$. Given a route flow, the corresponding link flow is easily computed as $f_a = \sum_{r \ni a} h_r$, for each $a \in \mathcal{A}$. For a flow f , the travel cost along

a route r is $c_r(f) := \sum_{a \in r} t_a(f_a)$. Let X be the set of feasible flows (f, h) and X_f its projection into the space of arc flows. Note that this set is a polytope given simply by the flow-conservation constraints for each commodity on every node (see **Multicommodity Flows** and Ahuja *et al.* [11]).

Interpreting Wardrop's first principle as requiring that all flow travels along shortest paths, a flow h is called a *Wardrop equilibrium* if and only if for all $k \in \mathcal{C}$, we have that

$$c_r(h) = \min_{q \in \mathcal{R}_k} c_q(h), \quad (1)$$

for all $r \in \mathcal{R}_k$ such that $h_r > 0$. Beckmann *et al.* [7] proved that such a flow always exists by considering the following min-cost multicommodity flow problem with separable objective function:

$$\min \left\{ \sum_{a \in \mathcal{A}} \int_0^{f_a} t_a(z) dz : f \in X_f \right\}. \quad (2)$$

The previous problem is convex because the objective is the integral of a nondecreasing function and, since its domain is a compact set, attains its optimum (for some background on convex optimization. Actually, it can be proved that its first-order optimality conditions are

$$c_r(h) \leq c_q(h), \quad \text{for all } k \in \mathcal{C} \text{ and all routes } r, q \in \mathcal{R}_k \text{ such that } h_r > 0, \quad (3)$$

which is equivalent to Equation (1).

If cost functions t_a are strictly increasing, f is unique (but there can be different flow decompositions h). For the case of nondecreasing costs, the vector of costs $(t_a(f_a))_{a \in \mathcal{A}}$ is unique under the possibly nonunique equilibria. Computationally, Equation (2) implies that an equilibrium can be computed efficiently using general convex optimization techniques (see the section titled "Computation of Wardrop Equilibria")¹. A formulation similar to the one presented here can be used to perform

a sensitivity analysis of Wardrop equilibria, which can be useful when testing the robustness of the model [12].

Yet another important characterization of traffic equilibrium problems, due to Smith [13], consists of reformulating Equation (2) as a variational inequality problem, see also Dafermos [14] and **Variational Inequalities**. Accordingly, a flow f is a user equilibrium if and only if

$$\sum_{a \in \mathcal{A}} t_a(f_a) f_a \leq \sum_{a \in \mathcal{A}} t_a(f_a) x_a, \quad \text{for all flows } x \in X_f. \quad (4)$$

Note that this inequality is a direct consequence of the fact that in equilibrium, users travel on shortest paths with respect to arc costs $t_a(f_a)$. Another reformulation that is useful to characterize equilibria in very general settings is given by nonlinear complementary problems [15] (see **Complementarity Problems**).

Charnes and Cooper [16] were the first to notice that the concepts of Nash and Wardrop equilibria are related. Haurie and Marcotte [17] prove that a Nash equilibrium in a network game with a finite number of players converges to a Wardrop equilibrium when the number of players increases (for some background on game theory, see the section titled "Noncooperative Strategic-Form Games" in this encyclopedia). For this reason, although the solution concepts are different, a Wardrop equilibrium can be viewed as an instance of a Nash equilibrium in a game with a large number of players. De Palma and Nesterov [18] look at generalizations and alternative definitions of the basic model and established conditions that guarantee the existence of equilibria. For example, Wardrop equilibria still exist if cost functions are only required to be lower semicontinuous. Marcotte and Patriksson [19] also discuss alternative definitions of equilibria in network games and the relationships between them.

though, uniqueness is not guaranteed even as flow on arcs because Equation (2) is not necessarily a convex problem and hence, may admit multiple local optima.

¹In the case of nonmonotone costs, the solutions to Equation (2) are also equilibria. In this case,

To conclude, let us note that in practice a transportation planner needs to find or estimate all the elements that comprise the model. The topology of the network is usually digitized from maps, if it is not already available. Link travel cost functions are calibrated from historical information using tabulated functions that relate geometry of the road to capacity [20,21]. One may need to also add tolls or other generalized costs to the arcs, which can be converted to the same units by using the average value of time for the population. The latter can usually be estimated from socioeconomic information coming from census data. Demand can be measured directly or may come from historical OD matrices that can be calibrated using up-to-date traffic counts [8].

MORE GENERAL MODELS

Many extensions of the model presented in the previous section have been analyzed and studied since the introduction of the Wardrop equilibrium model in 1952. We now present a selection of extensions we believe are particularly interesting.

An important generalization consists in allowing link travel cost functions to depend on the full vector of flows. In that case, the function that represents congestion can be encoded by the operator $t(f) : \mathbb{R}_{\geq 0}^A \rightarrow \mathbb{R}_{\geq 0}^A$. This is of practical relevance because the cost in one arc usually depends on the load in other arcs. Typical examples in the area of transportation modeling include representing intersections more accurately when cross streets influence each other, and two-way streets where traffic going one way can impact the reverse lanes. Furthermore, to consider different vehicle types interacting in the same network, one can create one copy of the network per vehicle type and have congestion depend on the full load, defined as the weighted sum across all copies. An example in the area of wireless telecommunications is interference, which can make delays of nearby cells grow. In the nonseparable case, it is convenient to require that the operator t is monotone, meaning that $(t(f) - t(f')) \cdot (f - f') \geq 0$, for all

$f, f' \in \mathbb{R}_{\geq 0}^A$, a generalization of monotonicity in the separable case. We say that costs are nonseparable, symmetric when for any two arcs, the influence of traffic in one arc to the congestion on the other is equal to the reverse influence (with symbols, $\partial t_a(f)/\partial f_b = \partial t_b(f)/\partial f_a$, for all $a, b \in A$ and all $f \in \mathbb{R}_{\geq 0}^A$). In that case, the integral in Equation (2) can be replaced by $\int_0^f t(z) dz$, which is well defined, and an equilibrium can still be computed using convex optimization techniques. An easy example of this case is when $t(f) = \Theta f + \theta$, with Θ a symmetric matrix of dimension $|A|$. It is worth noting that this symmetry condition is equivalent to the requirement that the game is *potential* with a continuum of agents [22] (for an introduction to potential games, the reader is referred to Monderer and Shapley [23]). In the general asymmetric case, the equilibrium cannot be formulated as a convex optimization problem (but note that there are exceptions and in some cases they can be formulated as nondifferentiable optimization problems [24]) and one has to resort to abstractions such as variational inequalities and non-linear complementarity problems. Indeed, Equation (4) still holds and can be used to prove existence and uniqueness results, as well as a way to compute equilibria.

Another important extension to the basic model that goes in a different direction is referred to by elastic demands. A network model normally represents a spectrum of options that a user of the system has. In reality, a user will normally have more alternatives than those present in a model. For example, in a car transportation model, some users may decide to take a subway when roads are too congested or cancel the trip when the combination of travel time, tolls, and gas exceeds the utility of the trip. This can be captured by a model with a demand of users that will participate only when their willingness to pay is higher than the cost of trips. In this case, the link travel cost functions in the equilibrium model are complemented by a demand function $\delta_k(\cdot) : \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}_{\geq 0}$ per OD pair $k \in C$. This function specifies that when the cheapest route cost for OD pair k is π_k , its demand equals $\delta_k(\pi_k)$. Hence, an equilibrium jointly satisfies

Equation (1) and $d_k = \delta_k(\min_{q \in \mathcal{R}_k} c_q(h))$. Depending on the separability of the costs, both the optimization and variational inequality problems can be extended to solve models with elastic demand.

Finally, several authors have looked at other ways to relax some of the basic assumptions. We mention a few examples here. A classical extension to the basic model incorporates capacity and other side-constraints to the equilibrium model [25] as a way of improving the solution quality and correcting the link travel cost functions so as to bring the flow pattern into agreement with the anticipated results. This can be handled by adding the constraints to the formulations and reinterpreting their dual variables as queueing delay caused by congestion. However, this approach is controversial and several authors have looked at alternative models that work better in some situations [26]. Also, Gabriel and Bernstein [27] studied the case of nonadditive models where the cost of a path can be given by more general expressions than just the sum over all arcs in the path. Examples of this include taking into account the variability of travel times and risk-aversion [28], tolls, and valuation of time.

COMPUTATION OF WARDROP EQUILIBRIA

In this section, we discuss some computational approaches to finding Wardrop equilibria. Let us start by describing the Frank–Wolfe method [29], which is a traditional algorithm that has been used to compute equilibria. It is an iterative descent method that works with the formulation shown in Equation (2) and eventually converges to the equilibrium. The algorithm keeps a current solution, and solves a linearized version of Equation (2) at every step to determine a feasible descent direction. Referring to the objective of that problem by $T(f)$ and to the current solution by f^i , the linearized objective is $T(f^i) + \nabla T(f^i) \cdot (f - f^i)$. The linearization enables the algorithm to decompose the problem by OD pairs, allowing it to find a shortest path in $\mathcal{R}_k$ for each commodity $k \in \mathcal{C}$ independently of each other. To identify the steepest descent

direction, it computes a shortest path with respect to the prevailing traffic conditions. In the subsequent line search, the original nonlinear problem is solved restricted to the segment defined by the feasible direction of descent. The algorithm terminates when a certain precision is achieved. To determine when this is the case, the convexity of the objective function is used to derive a lower bound on the value of an optimal solution. Alternatively, one can compute the *gap*—defined as the deviation from the shortest path—in the current solution and terminate when it is smaller than a threshold. It is well known that this algorithm always converges to a global minimum because Equation (2) is a convex program.

The standard Frank–Wolfe algorithm sometimes shows poor convergence because it tends to zigzag around the equilibrium solution [8,30–32]. Because “... the (Frank–Wolfe) algorithm is considered sufficiently good for practical use” [30, p. 100], most of the commercial implementations use this procedure. Still, there are many algorithms that were developed to address the slow convergence times. Below, we summarize a few of the main approaches.

LeBlanc *et al.* [33] introduced an improved version of the previous algorithm called *Partan* (parallel tangents), which was further studied by Florian *et al.* [34] and Arezki and Van Vliet [35], among others. This improvement is based on a more intelligent line search. It determines the descent direction using the results of two consecutive iterations, thereby diminishing the zigzagging effect. These two methods belong to a class called *partial linearization algorithms* in which the objective function is simplified to be able to find a search direction.

The structure of Equation (2) leads to *decomposition algorithms*, which separate the main problem into subproblems. The Frank–Wolfe algorithm is an example of this general method since it considers OD pairs separately after fixing the prevailing flows in one iteration. But the separation can be done in other ways, and viewed as a block version of the Gauss–Seidel and Jacobi algorithms. For example, a common decomposition separates flows by node of origin, whereby

every iteration assigns all destinations for each origin at the same time. A good example of this approach is given by Bar-Gera's algorithm [36], which is one of the most efficient, in existence, to compute Wardrop equilibria.

The class of *column generation algorithms* deal with a path formulation of the model. Since it is computationally challenging to keep track of the flow along all routes as opposed to maintaining a vector of flows per arc, instead of having one variable per route initially, a column generation algorithm adds routes at the time they are needed. After discovering new routes with the search direction procedure, an algorithm of this type forms a *restricted master problem* that consists of a path formulation of Equation (2) using only the routes discovered thus far (see also **Column Generation**). These methods are especially important when costs along routes are not additive or when there are constraints based on paths because an arc formulation is not powerful enough to represent the problem in that case. The class of *simplicial decomposition* algorithms finds the next iterate using the restricted master problem. Since all the route information previously computed is badly utilized by algorithms that perform line search, this class can solve problems more efficiently, albeit doing more work per iteration.

The *method of successive averages* is a commonly used heuristic method for computing Wardrop equilibria. This method starts by computing the costs on all arcs for an arbitrary feasible flow. Iteratively, it computes a new solution using an auxiliary linear program that keeps costs fixed, and updates the current solution by averaging it with the new one using a factor that depends on the iteration. This technique is specially useful for more complicated models where exact techniques are not readily available. Some examples are the dynamic and stochastic traffic assignments, see the section titled "More Advanced Models".

The case of elastic demands can be incorporated in the previous discussion since it involves adding another term to the convex minimization problem. The case of nonseparable, symmetric cost functions can be handled similarly to what was described earlier

since it admits a convex program formulation. In contrast, the asymmetric case, requires the machinery of variational inequalities or nonlinear complementarity problems. There exist standard algorithms to solve these classes of problems and some of the variants presented earlier for the separable case can be extended to this setting. Notice that since the nonseparable case does not admit a convex programming formulation, checking convergence must rely on regret or other related measures.

The search for efficient algorithms to compute Wardrop equilibria for the various classes of models is a very active area of research. Some of the latest efficient approaches are due to Dial [37], Florian *et al.* [38], Gentile [39], and Bar-Gera [40]. To conclude the discussion on computation, we note that there are some test problems available in the *Transportation Network Test Problems* website [41] that are typically used to study new algorithms.

There exist many commercial software packages that implement some of the algorithms described in this section. These and some additional packages also implement other variants of traffic assignment problems such as dynamic models that explicitly incorporate time [42–44], and simulation models that consider finer behavioral details that analytical models cannot handle [45]. A nonexhaustive list of software implementations is AIMSUN, CUBE, CONTRAM, DYNAMIT, DYNASMART, EMME/2, PARAMICS, TRANSCAD, TRANSIMS, TSIS-CORSIM, SATURN, VISUM-VISSIM, VISTA, and UROAD-UTPS.

EFFICIENCY OF WARDROP EQUILIBRIA

Since an equilibrium model considers that users unilaterally choose their routes to minimize *their* route cost, the solution is not necessarily efficient. A natural question is thus to quantify how inefficient a Wardrop equilibrium may be, where efficiency is measured as the flow's total travel time $C(f) := \sum_{r \in \mathcal{R}} c_r(h) h_r = \sum_{a \in \mathcal{A}} t_a(f_a) f_a$. Following Wardrop's second principle [5] that states that users minimize the total travel

time in the system, a system optimum f^* is an optimal solution to the min-cost multicommodity flow problem:

$$\min \{C(f) : f \in X_f\}. \quad (5)$$

It is not hard to observe that, in general, the total travel time incurred by an equilibrium can be arbitrarily larger than that of a social optimum. Consider, for instance, a two-node two-link network with unit demand and cost functions given by $t_1(f_1) = 1$ and $t_2(f_2) = f_2^n$, for some large value of n (Fig. 1). At equilibrium, all flow will use the second link, so that the total travel time will be 1. On the other hand in the system optimum a small fraction of the flow will use the first link, so that its total travel time will be close to 0, making their ratio grow to infinity. Nevertheless, a sequence of results initiated by Roughgarden and Tardos [46] and further developed in papers [47–51] states that if we only allow link travel cost functions belonging to a certain class, then the total travel time of an equilibrium is at most a constant times that of the system optimum.

Let us illustrate this group of results by considering the case in which for all $a \in \mathcal{A}$, $t_a(\cdot)$ is an affine function with nonnegative coefficients. Consider an equilibrium flow f and a system optimal flow f^* , then we have that

$$\begin{aligned} C(f) &\leq \sum_{a \in \mathcal{A}} t_a(f_a) f_a^* = \sum_{a \in \mathcal{A}} t_a(f_a^*) f_a^* \\ &\quad + \sum_{a \in \mathcal{A}} f_a^* (t_a(f_a) - t_a(f_a^*)) \leq \sum_{a \in \mathcal{A}} t_a(f_a^*) f_a^* \end{aligned}$$

Figure 1. Instance where the Wardrop equilibrium is unboundedly worse than the system optimum.

$$\begin{aligned} &+ \sum_{a \in \mathcal{A}: f_a > f_a^*} f_a^* (t_a(f_a) - t_a(f_a^*)) \\ &\leq \sum_{a \in \mathcal{A}} t_a(f_a^*) f_a^* + \frac{1}{4} \sum_{a \in \mathcal{A}} t_a(f_a) f_a, \end{aligned}$$

implying that $C(f) \leq (4/3) \cdot C(f^*)$. The first inequality in the previous derivation holds because of Equation (4), while the last inequality follows since for affine functions the shaded area in Fig. 2 is at most 25% of the area of the big rectangle. This theorem is due to Roughgarden and Tardos [46], and the short proof presented here appeared in Correa *et al.* [49]. The result implies that, in the worst case among all possible networks, the inefficiency introduced by the self-minded behavior of an equilibrium is never worse than 1/3.

The proof above easily extends to other classes of link travel cost functions by only changing the 25% with the corresponding quantity for a given class of functions. Probably the most interesting aspect of this result is that the efficiency loss depends on the allowable functions rather than on the topology of the network. Furthermore, the idea behind this proof provides another interesting result first derived in Roughgarden and Tardos [46]. Indeed, note that if $t_a(\cdot)$ are arbitrary non-decreasing functions, then $\sum_{a \in \mathcal{A}} x_a t_a(f_a) \leq$

Figure 2. Illustration of the proof of the 4/3 result.

$\sum_{a \in A} \max\{f_a t_a(f_a), x_a t_a(x_a)\} \leq \sum_{a \in A} f_a t_a(f_a) + \sum_{a \in A} x_a t_a(x_a)$, where the f_a 's and x_a 's are any nonnegative numbers. Consider now an equilibrium flow f of a given instance, and a system optimal flow x of a similar instance where demands rates d are doubled. From Equation (4), and since $x/2 \in X_f$, we have

$$\begin{aligned} C(f) &= 2C(f) - C(f) \leq 2 \sum_{a \in A} t_a(f_a) \cdot (x_a/2) \\ &\quad - C(f) \leq \sum_{a \in A} t_a(f_a) \cdot x_a - C(f) \leq C(x). \end{aligned}$$

In other words, for arbitrary nondecreasing link travel cost functions, the cost of a Wardrop equilibrium is at most the cost of an optimal solution with the demand doubled. For a restricted set of cost functions, one can provide improved results [49]. For example, under affine costs one can prove that the same statement holds with 25% more demand.

As general equilibria typically do not minimize the social cost, Koutsoupias and Papadimitriou [52] proposed to analyze the inefficiency of equilibria from a worst-case perspective; this led to the notion of “price of anarchy” [53], which is the ratio of the worst social cost of a Nash equilibrium to the cost of an optimal solution. In the context of our traffic model this quantity has been analyzed in a series of papers for increasingly more general classes of cost functions and other model features. The result previously described implies that this worst-case ratio is 4/3. This was extended to more general link travel cost functions by Roughgarden [47] and by Correa *et al.* [48], who basically proved that the efficiency loss in this setting is independent of the topology of the network. Chau and Sim [50] considered the case of nonseparable, symmetric cost functions with elastic demands. They proved that the efficiency loss can be bounded in a similar way as what is described here. Perakis [51] considered general nonseparable cost functions and proved upper bounds using variational inequalities as well. Her bounds depend on two parameters that measure the asymmetry and the nonlinearity of the cost functions considered. Farzad *et al.* [54] provide results of a similar flavor in a closely related model. In their setting the flow

(players) have a priority and thus, in any given link a flow particle only experiences a travel time $t_a(x_a)$, where x_a is the amount of flow using link a , having higher priority. Interestingly in this context a system optimum is given by Equation (2).

MORE ADVANCED MODELS

This section discusses some extensions of the basic Wardrop equilibrium model that consider variations on the structure of offer and demand in the network.

In most urban transportation networks, commuters do not have to pay the cost they impose to others by a particular route choice, leading to the bad utilization of the available capacity alluded to in the section titled “Efficiency of Wardrop Equilibria”. Since congestion increases sharply with road utilization, having relatively few drivers switch to other routes may significantly improve commute times. Starting with the seminal idea of Vickrey [55,56], many transportation economists have advocated the use of congestion pricing to achieve this goal. The scheme forces drivers to pay a toll when entering congested areas. The underlying idea is to charge drivers the externality they impose to others because when commuters internalize these externalities, the corresponding choices maximize the system welfare. Singapore introduced congestion pricing in 1975, London in 2003 [57,58], and Stockholm in 2007. Increasingly, many large cities have been debating whether a congestion pricing scheme should be adopted. Nevertheless, it has been very hard to implement congestion pricing because of technical, economical, and political problems. There is a large body of research on finding the set of tolls for a given network that optimizes a given objective (e.g., social welfare, revenue, number of tollbooths) under constraints (such as a budget balance, maximum number of tollbooths, or restrictions on their location). For more details, see the books [59,60].

Stochastic user equilibrium models date back to the 1970s, when Dial [61] proposed a model where the demand on each OD is distributed among routes (with random lengths)

according to a logit distribution, in the case of uncongested traffic networks. To reduce route enumeration he considered that flow is distributed only among “efficient routes.” This model has been widely studied and extended [62,63]. Furthermore, Daganzo and Sheffi [64] looked at the case of dependent route costs, while Fisk [65] studied the model in the context of congested networks, obtaining an equivalent optimization problem. Methods avoiding route enumeration have been proposed by Bell [66], Larsson *et al.* [67], and Maher [68], also leading to equivalent optimization problems in the spirit of Fisk’s. Based on the work of Akamatsu [69], Baillon and Cominetti [70] proposed a more general concept called *Markovian traffic equilibrium*, provided an equivalent optimization problem, and established the convergence of the method of successive averages in that context. There are complementary models that consider that travel times themselves are stochastic instead of considering that the perception is stochastic. Some examples are the papers [28,71–75].

Another important extension is modeling public transportation systems. The time commuters need to wait until a bus arrives to the stop adds a difficulty that was not present in models of privately owned vehicles. Indeed, in order to balance waiting and travel time, users’ strategies may involve selecting a subset of bus lines and boarding the first available one. This idea was pioneered by Chiriqui and Robillard [76], who considered a network with a single OD pair and n bus lines serving it, each characterized by a travel time and a frequency. They provided a simple efficient algorithm to solve the problem. Spiess and Florian [77] generalized that model to arbitrary networks introducing the notion of general users’ strategies. This was further put in graph theoretic terms by Nguyen and Pallotino [78], who called these strategies *hyperpaths* and incorporated travel times dependent on congestion. However, besides increasing travel times, congestion also increases waiting times because a user may not be able to board a selected bus. This is challenging and Wu *et al.* [79] and Bouzaïene-Ayari *et al.* [80] attempted to deal with this problem. Cominetti and Correa [81]

considered the frequency of a bus line as a function of the flow in the network and called this function ‘*effective frequency*.’ They proved that an equilibrium in this context exists via an equivalent optimization problem. Cepeda *et al.* [82] obtained a new characterization of equilibria in the congested setting. This led to an effective algorithm that is currently part of EMME/2.

In some situations, such as logistics networks, it is natural to consider that some players control nonnegligible amounts of flow that can be split among several routes, as modeled by an *atomic* network game [83]. In this context, the equilibrium becomes significantly more difficult to characterize and compute because, even for the basic assumptions, the game is generally not potential. Although the existence of equilibria is still guaranteed [84], an instance may possess multiple equilibria [85], and no equivalent convex optimization problem is known even for general separable instances. Furthermore, surprisingly an equilibrium of this game can be less efficient than that of the corresponding nonatomic instance (as in the section titled “The Basic Model”), even in simple networks with two OD pairs [86,87]. Cominetti *et al.* [87] generalized the results of the section titled “Efficiency of Wardrop Equilibria” to this setting, getting a bound of $3/2$ when cost functions are affine. It is an open question whether this bound is tight. Swamy [88] proved that tolls that induce an optimal routing of the game with finite players always exist.

Generalizing a classic paper by Rosenthal [89], Milchtaich [90] considered a generalization of the basic model referred to by *congestion games*. In this model the network is abstracted away and each user selects a strategy that consists of a subset of arcs (instead of a route), selected among a set of feasible strategies defined in advance. The defining characteristic of these models is that a link travel cost function for one arc just depends on its demand. Milchtaich himself and others have looked at existence, uniqueness, and computation of equilibria in congestion games with and without atoms, and with homogeneous and heterogeneous cost functions. Actually, some of the results presented

in the section titled “Efficiency of Wardrop Equilibria” were originally presented for this kind of model.

Finally, another important area of research involves extending the basic model along the time dimension. Starting with the seminal work of Merchant and Nemhauser [42], many articles have been published about *dynamic user equilibria*. These models consider time-varying conditions on both the offer and demand side of the network. In contrast to the static model discussed here, there is less agreement on the basic characteristics of the model, and on the conditions that such a model should verify, which highlights the difficulty of the problem. Nevertheless, transportation planners commonly make use of tools that rely on analytic or simulation models of this kind. We refer the readers to Ran and Boyce [91], Peeta and Ziliaskopoulos [44], and the report by the Transportation Research Board [92] for more details about dynamic models.

Another relevant issue related to equilibria in general, and to Wardrop equilibria, in particular, is whether players “learn” the equilibria of the game and if so, how fast they do it. There is a rich literature mainly concerned with the dynamics that govern the behavior of players. The book by Sandholm [93] contains an in-depth treatment of the subject. In particular, he describes some learning dynamics under which players of a congestion game, such as those described in this article, converge to an equilibrium. Related to learning and equilibria, there has been limited empirical work to validate whether test subjects behave as the theory of Wardrop equilibria predicts they do [94–98].

FURTHER READING

For an extensive discussion on modeling and algorithmic techniques, we refer the reader to Magnanti [99], Sheffi [8], Nagurney [100], Patriksson [30], Florian and Hearn [31], and Marcotte and Patriksson [19]. Altman *et al.* [10] surveys the use of this framework in modeling telecommunication networks. Nisan *et al.* [101] and the references therein provide details on the efficiency of equilibria in network games.

Acknowledgments

We would like to thank a referee, Patrice Marcotte, and Bill Sandholm for numerous suggestions and comments regarding an earlier version of this article.

WARRANTY MODELING

MARLIN U. THOMAS
Department of Electrical and
Computer Engineering, Air Force
Institute of Technology,
Wright-Patterson AFB, Ohio

Warranties are binding commitments by producers to provide acceptable quality of their products or services for some prescribed period of time following the sale or delivery of the goods. Product guarantees and warranties have been around as far back in time as is known to mankind, but it has only been during the past few decades that quantitative methods have evolved for analyzing and evaluating economic decisions relating to warranties. The early analysis methods were focused on product marketing, and accounting for the amount of warranty expenditures that should be included in manufacturing costs. However, as competition grew and became more global, manufacturers and service providers had to become more quality focused thereby making quality and warranty essential elements of corporate planning. Customers rely on warranties for protection against low quality products and manufacturers use them for marketing and building confidence in their products for purposes of market penetration and being competitive. The difficulties and challenges in providing suitable warranty programs and hence support for the need for modeling are: (i) developing appropriate product warranty policies, (ii) methods for predicting associated warranty costs and future burdens, and (iii) methods for planning quality and reliability improvement options. The relevant economic issues in dealing with these problem areas involve risk due to uncertainties in the customer preferences and expectations, and the failure characteristics of the products. Details on the history and background on warranties can be found in Refs 1 and 2.

This article provides an overview of the quantitative models for examining

economic decisions that involve warranties. Warranty models are constructed relative to the customer's costs and benefits from the warranty, or to that of the producer of the products. Throughout this article, the models will reflect the position of the producer or manufacturer. In the section titled "Product Warranties" we discuss the types of product warranties and provide an account of the basic policies that are applied to consumer products. In the section titled "Warranty Cost Models," warranty economic models developed for cost considerations under various types of warranty policies, examining optimal policies, and determining reserve funds for covering future warranty costs are discussed. We will then cover models for dealing with machine replacement and maintenance decisions. It should be noted that while our focus is still with the manufacturer's cost considerations for these models, the manufacturer is actually the customer whose goal is to maintain operational equipment, some of which is under warranties. Finally, we will provide summary remarks that will include comments on some ongoing and future modeling directions.

PRELIMINARY ASSUMPTIONS AND NOTATION

1. A warranty claim is filed each time a product failure occurs during the warranty period.
2. Failure times, T are independent and identically distributed (iid) with common probability distribution F .
3. Failure cost X_i can depend on failure time T_i but the pairs, (X_i, T_i) form an independent sequence for $i = 1, 2, \dots$

PRODUCT WARRANTIES

A warranty is a form of agreement between parties with specified conditions for: (i) the length of time during which the warranty is

to be in effect, (ii) the method of compensation for the product or service during the warranty period, and (iii) the conditions for which the warranty will apply or will not apply to the product or service. The parties are generally between customers and a producer or manufacturer, although it could also be between customers and a brokerage organization other than the producer. From a modeling perspective, the first two specifications, period of coverage and method of compensation are the salient issues for decision models with the third category being a descriptive category for the various types of warranties.

There are two distinct types of warranties relative to the period of coverage. Most consumer warranties are for a *fixed period* of time that is measured in age or product usage from the date of purchase. For a warranty of length $w > 0$, the coverage applies only for reported warranty failures during the period $(0, w]$. The second type of warranties is the class of renewable or *renewing period* warranties whereby the initial period of coverage is $(0, w]$ but when a failure occurs within this warranty period a new warranty is granted. This process is repeated until the item survives a time of length w . Sample realizations of nonrenewing and renewing period warranties are shown in Fig. 1. Renewing period warranties are generally applied to relatively inexpensive products that have a very low likelihood of failure during the warranty period. They are less common than fixed period warranties.

Free Replacement Warranty (FRW)

The most common compensation methods are based on one of the compensation schemes. The first and simplest is the class of free replacement policies, whereby the cost of repair or replacement of the warranted item is completely covered by the manufacturer during the warranty period. Let T be a non-negative random variable representing the time to failure of a product with a repair or replacement cost to the manufacturer of c dollars per unit. Under the free replacement warranty (FRW) policy, the unit cost to the manufacturer at time t , for a warranty of length $w > 0$ is

$$X(t) = \begin{cases} c, & 0 \leq t \leq w, \\ 0, & t > w, \end{cases} \quad (1)$$

where $f(t)$ and $F(t)$ are the probability density and distribution functions for T .

Prorata Rebate Warranty (PRW)

The second class of compensation policies is prorata rebate policies for which the costs of repair or replacement are shared by the customer and the manufacturer according to a prescribed prorate scheme. Prorata rebate warranty (PRW) policies, sometimes called *prorata replacement policies* are generally applied to products that are not repairable and the proportion of sharing between the manufacturer and the customer is a function of the age of the product at the time of failure. Under a PRW policy with a linear prorata function, an item that costs the manufacturer c dollars per unit that is sold with

Figure 1. Cycle time τ for non-renewing and renewing warranties.

a warranty of length $w > 0$ has a unit cost to the manufacturer at time t given by

$$X(t) = \begin{cases} c \left(\frac{w-t}{w} \right), & 0 < t \leq w, \\ 0, & t > w. \end{cases} \quad (2)$$

The customer must be willing to pay the residual amount of ct/w to execute this policy. The expected unit cost to the manufacturer is

$$E[X(t)] = c \int_0^w (1 - t/w) f(t) dt \quad (3)$$

or

$$E[X(t)] = cF(w) - \frac{c}{w} \int_0^w tf(t) dt. \quad (4)$$

where $f(t)$ and $F(t)$ are the probability density and distribution functions for T .

Combined FRW PRW

Another policy that is common to many products is a combined policy where a product is covered by an FRW policy for a period $(0, w_1)$ followed by a PRW policy during (w_1, w_2) . Denoting the initial cost of the item by c , the unit cost to the manufacturer for a warranty failure is given by

$$X(t) = \begin{cases} c, & 0 \leq t \leq w_1, \\ c \left(\frac{w_2-t}{w_2-w_1} \right), & w_1 < t \leq w_2, \\ 0, & t > w_2 \end{cases} \quad (5)$$

and the expected unit cost is given by

$$\begin{aligned} E[X(t)] &= cF(w_1) + \left(\frac{cw_2}{w_2 - w_1} \right) \\ &\quad \times [F(w_2) - F(w_1)] \\ &\quad - \frac{c}{w_2 - w_1} \int_{w_1}^{w_2} tf(t) dt. \end{aligned} \quad (6)$$

An alternate form of Equation (6) that is sometimes easier to work with follows by integrating the last term by parts and simplifying to obtain

$$E[X(t)] = \frac{c}{w_2 - w_1} \int_{w_1}^{w_2} F(t) dt. \quad (7)$$

Example 1. A product sold under a PRW policy has a failure time T distributed exponential with parameter $\lambda > 0$.

$$F(t) = 1 - e^{-\lambda t}, t \geq 0. \quad (8)$$

The expected unit cost from Equation (4) is

$$E[X(t)] = c - \frac{c}{\lambda w} (1 - e^{-\lambda w}). \quad (9)$$

Example 2. A product is sold under a FRW/PRW policy with unit costs given in Equation (5). The failure time T is distributed Weibull with

$$F(t) = 1 - e^{-(t/\theta)^\beta}, t \geq 0, \quad (10)$$

where $\beta > 0, \theta > 0$.

Substituting into Equation (8),

$$E[X(t)] = c - \frac{c}{w_2 - w_1} \int_{w_1}^{w_2} e^{-(t/\theta)^\beta} dt. \quad (11)$$

Warranties with Discounting

Cost models for products under relatively long warranty periods with high repair and maintenance costs should include the provision of the time value of money. Letting $\delta, 0 < \delta < 1$ be the discount factor, the expected discounted unit cost is

$$E[X_D(t)] = E[e^{-\delta t} X(t)]. \quad (12)$$

The expected discounted unit warranty cost from Equations (1) and (3) are given by

$$E[X_D(t)] = \begin{cases} c \int_0^w e^{-\delta t} f(t) dt, & \text{FRW,} \\ \frac{c}{w} \int_0^w \int_0^t e^{-\delta \tau} f(\tau) d\tau dt, & \text{PRW.} \end{cases} \quad (13)$$

Example 3. For the case of discounting, the cost for the PRW policy with T distributed exponential in Example 1, from Equation (13) is

$$\begin{aligned} E[X_D(t)] &= \frac{c}{w} \int_0^w \int_0^t \lambda e^{-\delta \tau} e^{-\lambda \tau} d\tau dt \\ &= \frac{c\lambda}{w} \int_0^w \frac{1 - e^{-(\delta + \lambda)\tau}}{\lambda + \delta} d\tau \end{aligned}$$

or

$$\begin{aligned} E[X_D(t)] &= \frac{\lambda c}{\lambda + \delta} - \frac{\lambda c}{(\lambda + \delta)^2} [1 - e^{-(\delta + \lambda)w}], w \geq 0. \end{aligned} \quad (14)$$

Example 4. Applying discounting for the FRW/PRW policy with T distributed Weibull in Example 2, the expected discounted unit cost from Equation (7) is

$$\begin{aligned} E[X_D(t)] &= \frac{c}{w_2 - w_1} \int_{w_1}^{w_2} \int_0^t \left(\frac{\beta}{\theta}\right) \left(\frac{\tau}{\theta}\right)^{\beta-1} \\ &\quad \times e^{-[\delta\tau + (\tau/\theta)^\beta]} d\tau dt. \end{aligned} \quad (15)$$

These integrals can be solved by standard numerical integration methods.

WARRANTY COST MODELS

Warranty related decisions can be critical for manufacturers since they relate directly to the quality and reliability of their products. Still there is always some level of risk that is inherent in product failures. It is important that product failure characteristics are well understood and known in advance of products being released to the markets. Methods are therefore needed to examine these issues in managing and planning warranty programs. The following models are useful for examining policy and planning resources for warranty expenditures.

Expected Warranty Costs

Consider a product that is sold under a warranty policy ϕ , which could be FRW, PRW, or FRW/PRW. The interarrival times for warranty failures T_i are iid $F(t), t \geq 0$ with failure costs $X_i(t), i = 1, 2, \dots$. The manufacturer's expected warranty cost is then given by

$$C(w, \phi) = E \left(\sum_{i=1}^{N(w)} X_i(t) \right). \quad (16)$$

It follows that $N(w)$, the number of warranty failures occurring in $(0, w)$ is a stopping time therefore,

$$E \left(\sum_{i=1}^{N(w)} X_i(t) \right) = E[N(w)]E[X_i(t)].$$

$E[X_i(t)]$ is the expected unit cost for warranty failures given by Equations (1), (4), and (6) for $\phi = \text{FRW}$, PRW , and FRW/PRW . Thus Equation (16) more generally is

$$C(w, \phi) = M(w)E[X_i(t)], \quad (17)$$

where

$$M(t) = \sum_{n=1}^{\infty} F^{(n)}(t) \quad (18)$$

is the renewal function and $F^{(n)}(t)$ is the n -fold convolution of $F(t)$ with itself.

When failure times T_i are exponentially distributed and hence $N(t)$ is distributed Poisson with rate $\lambda > 0$, the renewal function is simply $M(t) = \lambda t$. This particular case has practical appeal for warranty and reliability related applications, since new products are designed to perform during their useful lives. This however is one of only a few special cases for which $M(t)$ can be derived in closed form. In general, it can be computationally cumbersome to evaluate. Various numerical and approximation methods have been developed to overcome these computational difficulties for analyzing warranties [3–5], as well as other applications [6–8].

Economically Equivalent Policies

It is sometimes advantageous for analysis purposes to translate a PRW policy to the more simple FRW policy.

Proposition 1. *For a nonrenewing PRW policy defined over $I_1 = \{t : t \in (0 < w_1 \leq w_2 < \infty)\}$ there is a cost equivalent policy over $I_0 = \{t : t \in (0 < w < \infty)\}$, where $w_1 < w < w_2$.*

1. *Without discounting,*

$$w = F^{-1} \left(\int_{w_1}^{w_2} \frac{F(t)}{w_2 - w_t} dt \right). \quad (19)$$

2. *With discounting, w is the value satisfying*

$$e^{-\delta w} F(w) + \delta \int_0^w e^{-\delta t} F(t) dt$$

$$= \left(\frac{1}{w_2 - w_1} \right) \int_{w_1}^{w_2} \int_0^t e^{-\delta\tau} f(\tau) d\tau dt. \quad (20)$$

The proofs of (1) and (2) follow by equating the respective expected unit costs given in Equations (1) and (3) for (1), and in Equation (13) for (2).

Example 5. [9]. A machine is produced at a cost to the manufacturer of c dollars per unit and sold with a combined warranty of 6-month FRW followed by a 30-month PRW policy. Warranty failures are distributed exponential with a mean failure time of 30 months. The interest rate over the period is assumed to be 10%.

For T_i distributed exponential with parameter $\lambda > 0$, from Equation (20), it follows that

$$w = \frac{-1}{\lambda} \ln \left[\frac{e^{-\lambda w_1} - e^{-\lambda w_2}}{\lambda(w_2 - w_1)} \right]. \quad (21)$$

Substituting parameter values $\lambda = 0.02$, $w_1 = 6$, and $w_2 = 36$,

$$w = \frac{-1}{0.02} \ln \left[\frac{e^{-(0.02)6} - e^{-(0.02)30}}{0.02(36 - 6)} \right] \\ = 28.7 \text{ months.}$$

For the case of discounting, the right side of Equation (20) simplifies to

$$\left(\frac{1}{w_2 - w_1} \right) \int_{w_1}^{w_2} \lambda e^{-(\lambda+\delta)t} dt \\ = \left(\frac{\lambda}{\lambda + \delta} \right) \left[1 - \left(\frac{e^{-(\lambda+\delta)w_1} - e^{-(\lambda+\delta)w_2}}{(\lambda + \delta)(w_2 - w_1)} \right) \right].$$

Substituting the parameter values with $\delta = 0.1$ and $\lambda + \delta = 0.12$, it follows that

$$\frac{1}{6}(1 - e^{-0.12w}) = 0.145,$$

And $w = 17$ months.

Proposition 2. For a renewing period FRW/PRW policy defined over $I_1 = \{t : t \in (0 < w_1 < w_2 < \infty)\}$ there is a cost equivalent FRW policy over $I_0 = \{t : t \in (0 < w < \infty)\}$ such that

$$w_0 = F^{-1} \left(\frac{\int_{w_1}^{w_2} F(t) dt}{(w_2 - w_1) \bar{F}(w_2) + \int_{w_1}^{w_2} F(t) dt} \right). \quad (22)$$

Proof. For a renewing warranty the period of coverage is determined by the number of successive failures

$$N = (T_1 \leq w) \cap (T_2 \leq w) \cap \dots \cap \\ (T_{n-1} \leq w)(T_n > w),$$

which is distributed geometric with

$$g_N(n) = \bar{F}(w)[F(w)]^{n-1}, n = 1, 2, \dots$$

The mean number of failures in Equation (18) is therefore

$$M(w) = 1/\bar{F}(w), w \geq 0. \quad (23)$$

Substituting the expected unit cost from Equation (7) and the mean number of warranty failures from Equation (23) into Equation (17),

$$C(w, \text{FRW/PRW}) \\ = \frac{c}{\bar{F}(w_2)(w_2 - w_1)} \int_{w_1}^{w_2} F(t) dt. \quad (24)$$

For the FRW policy,

$$C(w, \text{FRW}) = \frac{cF(w_0)}{\bar{F}(w_0)}. \quad (25)$$

Equating these two expected costs and solving for w_0 leads to the result (Eq. (22)).

Example 6. A nonrepairable product is sold with a one year warranty, providing full coverage for the first 3 months with the remaining 9 months covered under a PRW policy. A new warranty is initiated when an item is replaced during the warranty period. Warranty failures are distributed exponential with mean time to failure of 15 months. The producer is considering offering a new warranty that would provide full coverage to customers without increasing cost.

For exponentially distributed failures, in Equation (22)

$$w_0 = F^{-1} \left(\frac{\int_{w_1}^{w_2} (1 - e^{-\lambda t}) dt}{(w_2 - w_1)e^{-\lambda w_2} + \int_{w_1}^{w_2} (1 - e^{-\lambda t}) dt} \right)$$

which upon simplifying

$$\begin{aligned} w_0 &= F^{-1} \left(\frac{(w_2 - w_1) - (1/\lambda)}{(e^{-\lambda w_1} - e^{-\lambda w_2})} \right) \\ &= F^{-1} \left(\frac{(w_2 - w_1)e^{-\lambda w_2} + (w_2 - w_1)}{-(1/\lambda)(e^{-\lambda w_1} - e^{-\lambda w_2})} \right). \end{aligned} \quad (26)$$

Substituting the values $w_1 = 3$, $w_2 = 12$, and $\lambda = 1/15$,

$$\begin{aligned} w_0 &= F^{-1} \left(\frac{(12 - 3) - (15)}{(e^{-3/15} - e^{-12/15})} \right) \\ &= F^{-1}(.3195) \end{aligned}$$

and it follows that the 1-year combined FRW/PRW policy could be replaced by an FRW policy over a $w_0 = 5.77$ month period.

Optimum Policies

The manufacturer's warranty cost for a product will increase over time from warranty failures and increasing failure rates (IFR) from aging. The choice of warranty length will depend on the benefit in providing the warranty. The manufacturer benefit is generally assessed through marketing studies, consumer surveys, and other studies that can be used to quantify benefit. One method is to assume for a given product that the benefit from a warranty will vary in a decreasing manner with the cost for marketing and advertising [9]. Denoting the expected benefit as a function of warranty length by $B(w)$ and the expected warranty cost by $C(w, \phi)$, $w \geq 0$ the expected total variable cost to the manufacturer is given by

$$T(w, \phi) = B(w) + C(w, \phi). \quad (27)$$

$C(w, \phi)$ is an increasing function in w , whereas $B(w)$ will decrease with increasing warranty intervals. The rationale is that the benefit to the manufacturer is realized through lower marketing costs for promoting a product with a short warranty in comparison to one for a longer duration. We assume that $B(w)$ and $C(w, \phi)$ are monotonic and $T(w)$ is convex.

Consider the case of an FRW policy with a quadratic benefit function

$$B(w) = (b_0 - b_1 w)^2, 0 \leq w \leq b_0/b_1. \quad (28)$$

The total expected cost is then

$$T(w) = cM(w) + (b_0 - b_1 w)^2, 0 \leq w \leq b_0/b_1. \quad (29)$$

Setting $\frac{d}{dw} T(w, \phi) = 0$, it follows that the optimum choice of warranty length w^* will satisfy

$$cm(w) + 2b_1^2 - 2b_0b_1 = 0, \quad (30)$$

where $m(w)$ is the renewal density function.

For the case of the warranty failure time T distributed exponential, the number of failures in $(0, w)$ is Poisson distributed, therefore $M(w) = \lambda w$ and from Equation (30), the optimum length for the warranty is given by

$$w^* = \frac{2b_0b_1 - c\lambda}{2b_1^2}. \quad (31)$$

Example 7. A nonrepairable item has a failure time T distributed according to an Erlang distribution with probability density function

$$f(t) = \lambda t e^{-\lambda t}, \lambda > 0, t \geq 0.$$

The mean time to failure is estimated to be 1.5 years. The unit warranty cost to the manufacturer for failures occurring during an FRW period of $(0, w)$ is \$1000. The warranty benefit function is assumed to be linear with the unit cost for marketing the product given by

$$B(w) = \$500 - 100w, w \geq 0.$$

For this case, the total expected cost in Equation (29) is given by

$$T(w) = cM(w) + (b_0 - b_1w), 0 \leq w \leq b_0/b_1. \quad (32)$$

For the Erlang distribution, it can be shown (Ref. 10, p. 170) that

$$M(t) = \frac{\lambda t}{2} - \frac{1}{4} + \frac{1}{4}e^{-2\lambda t}, t \geq 0.$$

Therefore in Equation (32)

$$T(w) = c \left(\frac{\lambda w}{2} - \frac{1}{4} + \frac{1}{4}e^{-2\lambda w} \right) + (b_0 - b_1w), 0 \leq w \leq b_0/b_1. \quad (33)$$

Setting $\frac{d}{dw}T(w) = 0$, leads to the optimum

$$w^* = \frac{1}{2\lambda} \ln(1 - 2b_1/c\lambda). \quad (34)$$

Substituting the parameter values $\lambda = 1/1.5$ failures per year, $c = \$1000$, $b_1 = \$100$ per year, and noting that b_0 does not enter the solution,

$$w^* = - \left[\frac{1}{2(1/1.5)} \right] \ln[1 - 2(100)/(500(1/1.5))] \\ = 0.267 \text{ years} = 3.2 \text{ months.}$$

Other approaches have been applied in exploring optimum pricing, warranty length, and marketing strategies under various assumed demand dependence on price and warranty [10], dynamic conditions [11], and marketing behaviors [12–14]. For more details on warranty management and economic models, see the reviews in Refs 2 and 15.

Allocating Warranty Reserve Funds

Warranty reserve is the collection of funds that are set aside to cover future expenses for warranty claims. The amount and process of withholding is important to the manufacturer because if insufficient funds are available for covering the expenses, profit shares will be affected and if too much is withheld,

then there will be lost opportunity for the company to make investments. The following method initially proposed by Menke [16] and later generalized by others [17,18] consists of creating a fund through the accumulation of a fixed proportion of unit sales.

Consider a product that is produced and sold in lot sizes of K units at a price of p dollars per unit under a PRW policy over $(0, w)$. The failure time probability density function, $g(t)$, $t \geq 0$ is assumed to be known. Denoting the rate of return and expected price change per period by ρ and π , the differential for the amount of reserve is given by

$$d(R) = X(t)d[K \cdot F(t)]. \quad (35)$$

The unit price p is the cost plus a constant amount of revenue, therefore, $X(t)$ for the PRW policy is given in Equation (2) and hence

$$d(R) = p(1 - t/w)(1 + \rho)^{-t}(1 + \pi)^{-t}K \cdot f(t)dt.$$

Noting that since

$$(1 + \rho)^{-t}(1 + \pi)^{-t} \rightarrow (1 + \rho + \pi)^{-t} = b^{-t},$$

it follows that

$$R(w) = \left(\frac{Kp}{w} \right) \int_0^w (w - t)b^{-t}f(t)dt. \quad (36)$$

Example 8. An item that is sold with a 1-year PRW policy has failure times T distributed exponential with a mean failure rate of 0.05 per year. Interest is assumed to be constant at 3% per period and price changes at a rate of 4% per period.

For T distributed exponential in Equation (36), it follows that the amount of reserve funds per unit of sale is given by

$$R(w) = \frac{Kp\lambda}{\lambda + \ln b} \left[1 - \frac{1 - b^{-w}e^{-\lambda w}}{w(\lambda + \ln b)} \right]. \quad (37)$$

With $\lambda = 0.05$ failures per year, $w = 1$ year, $\pi = 0.04$ and $\rho = 0.03$, $b = 1.07$, and

$$R(w) = \frac{Kp(.05)}{05 + \ln(1.07)} \left[\frac{1 - (1.07)^{-1}e^{-.25(1)}}{1(.05 + \ln(1.07))} \right] \\ = 0.024.$$

Therefore $R(1)/Kp = 0.024$, which indicates that 2.4% of the sales price should be held in a fund to cover the warranty expenses.

The process of collecting and managing reserve resources can be quite contentious, particularly when the consequences of not having sufficient funds to fulfill commitments are devastating to the organization. The challenge is in having accurate estimates of the amount needed in the fund. This method assumes that the distribution of failure times is known. Another approach is to develop the long run distribution of required reserves when warranty claims are assumed to follow a compound Poisson process [19]. These models are based on building a fund through accruals from sales that will be available to cover forthcoming warranty costs. Still, there is the problem of managing the flow of claims over time. Even adequately planned reserve collections can have significant shortfalls at various times due to the dynamics of the claims flow. One approach for overcoming this issue is to forecast the reserve fund requirement [20,21]. Buczkowski and Kulka-rni [22] developed a control policy based on allocating a fixed level of funds initially at the beginning of a period along with a fixed amount of accrual from each sale to ensure a positive reserve at a prescribed probability level. Ja *et al.* [23] derived results for developing optimal warranty length and reserve accruals for a minimal repair policy over $(0, w)$, to ensure the adequacy of reserves for covering the costs. Another interesting approach is to model and track the total warranty exposure time and total number of items under warranty over time [24].

WARRANTY AND MAINTENANCE DECISIONS

While active warranties are liabilities for producers, they are assets to customers. The models presented in this article so far have dealt with economic decisions for the producer or manufacturer of the products. We will continue to address the position of the manufacturer, only now the manufacturer is a user of the products under warranty.

We will now discuss models for maintenance planning decisions for items under warranty. The purpose of maintenance planning is to provide policy for maintaining operationally ready equipment that will ensure reliable and efficient service. The inclusion of warranties in these analyses will alter the allocation of costs between the producer and customer or manufacturer in this case, which can have a significant impact on the replacement decisions.

In its simplest form, the machine repair and replacement problem is to determine a policy for maintaining and replacing machines that are subject to deterioration over time. There is an extensive literature on maintenance and replacement strategies that dates back to the pioneering work of Barlow and Hunter [25]. However, it is only in recent years that warranty consideration has been included in these economic decision models. Most of the replacement and maintenance planning models are renewal theoretic based cost minimization models. The decision criterion for fixed-period non-renewing warranties is to minimize the expected total cost over the warranty period. For renewing warranties, the cost objective function is structured as a renewal reward process where the renewal cycle time is the random warranty period. The criterion is to minimize the long run average cost rate, estimated by the ratio of expected costs to expected cycle time.

Repair versus Replacement

Among the earliest reported results for modeling replacement decisions for machines under warranty is the work of Nguyen and Murthy [26]. They considered the problem of finding the optimum replacement time for a machine using the maintenance strategy of replacing the machine when failure occurs in an interval $(0, w - \alpha]$, and provide minimal repair maintenance when failure occurs in $(w - \alpha, w]$, where $0 \leq \alpha \leq w$. They showed that treating the failures as renewal events, the mean number of repairs in $(w - \alpha, w]$ is $M(w - \alpha)$ and the time to first failure beyond $(w - \alpha)$ is the excess life of the machine in use at time $(w - \alpha)$ which is distributed

$$F_\gamma(x) = F(w - \alpha + x) - \int_0^{w-\alpha} \bar{F}(w - \alpha + x - y) dM(y), x \geq 0. \quad (38)$$

The expected number of repairs during the minimal repair segment, $(w - \alpha, w]$ is given by integrating the failure rate function

$$\int_0^\alpha r_\gamma(x) dx = \int_0^\alpha \left(\frac{f_\gamma(x)}{\bar{F}_\gamma(x)} \right) dx = -\ln(\bar{F}_\gamma(x)).$$

Denoting the unit replacement and repair costs by c_s and c_r , the expected warranty cost is given by

$$C(\alpha, w) = c_s M(w - \alpha) + c_r \ln[1 - \bar{F}_\gamma(\alpha)]. \quad (39)$$

Setting $\frac{d}{d\alpha} C(\alpha, w) = 0$, the value α^* , providing the minimum expected warranty cost satisfies

$$\frac{\bar{F}(\alpha^*)}{\bar{F}_\gamma(\alpha^*)} = \frac{c_s}{c_r}, 0 \leq \alpha^* \leq w. \quad (40)$$

It is easily shown that for the case of exponentially distributed failure times, $\bar{F}(\alpha^*) = \bar{F}_\gamma(\alpha^*)$ in Equation (40) and hence $c_s/c_r = 1$. Computations are generally cumbersome but can be accomplished using numerical methods. An example for the case of Erlang distributed failures can be found in (Ref. 27, p. 391).

Age-Replacement for Renewing Warranties

Age-replacement is a strategy applied to units that are considered nonrepairable. By this strategy, an item is replaced when it fails at a time T or when it reaches a fixed time τ , whichever occurs first. Suppose the item is a piece of equipment that is not repairable, but is sold with a renewing FRW policy over $(0, w]$. Denoting the replacement cost by $c_s > 0$ and the cost of downtime during a failure by $c_d > 0$, for the case of $\tau > w$, the unit cost is given by

$$X(t) = \begin{cases} c_d, & t \leq w \\ c_s + c_d, & w < t < \tau \\ c_s, & t \geq \tau \end{cases} \quad (41)$$

So the owner of this equipment would never replace it as long as it is under warranty. With the further assumption that the failure times and related cost pairs, $[T_i, X(T_i)], i \geq 1$ are iid, this cost structure forms a renewal reward process (Ref. 28, p. 77). The optimal replacement time is the minimum long-term average cost, which is the ratio of the expected costs incurred during a cycle and the expected replacement cycle time. Since failure times are renewal events, the replacement cycles are also iid and of expected length $\int_0^\tau \bar{F}(u) du$. It follows that with renewing warranties the expected cost during a cycle is given by

$$C(\tau, w) = E[X(t)] = c_d F(w) + (c_s + c_d) \int_w^\tau f(u) du + c_s [1 - F(\tau)],$$

which simplifies to

$$C(\tau, w) = c_s \bar{F}(w) + c_d F(\tau). \quad (42)$$

The long run average cost rate is then

$$CR(\tau) = \frac{c_s \bar{F}(w) + c_d F(\tau)}{\int_0^\tau \bar{F}(u) du}, 0 < w \leq \tau. \quad (43)$$

To determine the optimum replacement time τ^* from this function, we first note that as $\tau \rightarrow 0$, $CR(\tau) \rightarrow \infty$ and as $\tau \rightarrow \infty$

$$CR(\infty) \rightarrow \frac{c_s \bar{F}(w) + c_d}{\mu}, \quad (44)$$

where μ is the expected product lifetime. It further follows from $\frac{d}{d\tau} CR(\tau) = 0$ in Equation (43) that for an IFR failure rate function $r(t)$, at the optimum replacement time $\tau^* > w$, $CR(\tau^*) = c_d r(\tau^*)$.

Example 9. A particular piece of nonrepairable equipment is purchased at a cost of \$5000 with $w = 1$ -year FRW policy. Failures that occur within the warranty period cost the owner \$1000 due to downtime, while the seller replaces the item along with a renewing warranty. The failure times are Weibull distributed with

$$F(t) = 1 - e^{-t^2}, t \geq 0.$$

For the Weibull distribution with characteristic value 1 and slope of 2, the mean lifetime $\mu = \sqrt{\pi}/2$. Substituting the parameter values with $c_s = \$5000$, $c_d = \$1000$, and $\bar{F}(1) = 0.3679$ into Equation (43), the long run average cost rate is

$$CR(\tau) = \frac{1864 + 1000(1 - e^{-\tau^2})}{\int_0^\tau e^{-u^2} du}, 1 < \tau < \infty, \quad (45)$$

and

$$c_d r(\tau) = 2,000\tau, 1 < \tau < \infty. \quad (46)$$

It follows that $CR(2.2) = 4.389$ and $1000r(2.2) = 4400$, therefore $\tau^* = 2.2$.

POSTWARRANTY MAINTENANCE

Service organizations such as job shops have to ensure that they have operational-ready equipment available when they need it for orders. During warranty periods, the reliability of production equipment is at its highest and failure costs are largely covered by the seller; therefore, equipment is generally not replaced until expiration of the coverage. It is of course possible that the relative costs involved in the previously discussed optimum replacement strategies are such that the optimum replacements are at an age $\tau < w$ [29]. In either case the proprietor or job shop owner faces a postwarranty decision on the level of maintenance necessary to keep the equipment operational and cost effective. One option is to avoid or delay implementing a maintenance program by extending warranties. These decisions are much the same as “own” versus “lease” decisions and optimality conditions for given cost and failure characteristics have been developed for examining these options [30]. Maintenance program options can vary from minimal repair and replacement strategies [31] to extensive preventive maintenance (PM) programs for extending the lifetime of the equipment. Like age-replacement, maintenance planning models are renewal theory based with the cost and failure events treated as renewal rewards.

Jung and Park [32] developed conditions for optimum periodic PM following warranty coverage. Consider a machine under an FRW renewing policy of length w with failure time T distributed $F(t)$ and failure rate $r(t)$, that is, IFR. Starting from the expiration of the warranty, the cycle length is $T < w$ if failure and replacement occurs during the initial warranty period. If the item survives to w , $T > w$ then the cycle is extended by a fixed number of periodic PM actions of length τ . The expected cycle time for an item replaced at PM cycle time N is then

$$\begin{aligned} E[T(\tau, N)] &= E(T|T < w)F(w) \\ &\quad + E(w + N\tau|T > w)\bar{F}(w) \\ &= \int_0^w tf(t)dt + (w + N\tau)\bar{F}(w), \end{aligned} \quad (47)$$

During $(0, w)$, there are no costs to the user but for $T > w$ the costs for minimum repair, PM, and replacement are incurred. From earlier studies [28], the expected cost for minimum repairs between scheduled PM actions is given by

$$\begin{aligned} E(C_m) &= c_m \bar{F}(w) \left\{ \frac{N(N-1)}{2} \tau [r(w + \tau) - r(w)] \right. \\ &\quad \left. + N \int_w^{w+\tau} r(t)dt \right\}, \end{aligned}$$

where c_m is the unit cost of PM and the expected end of cycle replacement cost is $c_r \bar{F}(w)$. The long run average maintenance cost rate is then given by

$$\begin{aligned} CR(\tau, N) &= \left[\begin{aligned} &c_{PM}(N-1)\bar{F}(w) \\ &+ c_r \bar{F}(w) + c_m \bar{F}(w) \\ &\left\{ \frac{N(N-1)}{2} \tau [r(w + \tau) - r(w)] \right. \\ &\quad \left. + N \int_w^{w+\tau} r(t)dt \right\} \end{aligned} \right] \\ &\quad \times \left[\int_0^w tf(t)dt + (w + N\tau)\bar{F}(w) \right]^{-1}, \end{aligned} \quad (48)$$

where c_{PM} is the unit cost for PM. The authors show that for $r(t)$ strictly increasing and convex the optimum period length and number

of PM cycles (τ^* , N^*) can be derived. Further details on PM under various warranty conditions can be found in Ref. 33.

SUMMARY REMARKS

1. The models presented in this article deal with management and operations issues that involve product warranties. The perspective taken for the cost models is that of the producer or the manufacturer. The maintenance planning models however reflect the perspective of the customer, which is often also the manufacturer or producer. Much of the literature on warranty models includes consumer objectives as well.
2. Warranty failures and related costs are directly related to the overall effectiveness in producing products and services relative to quality and customer expectations. Consequently, important feedback information can be derived from warranty programs for planning quality improvement and serving as a management control element for the manufacturing system. Warranty information is used as a relative indicator of cumulative costs and areas for identifying reliability improvements options. There is need for more quantitative methods for developing performance tracking and improvement strategies [34].
3. This broader view of treating warranty as an integral element of a product system suggests several directions for further developments. One area of need is to better understand the classes of customer behavior effects including risk aversion to warranty options. Very little work has been done in characterizing reactions to warranty options [20]. Postwarranty options in particular are risk options that can provide mutual opportunities for both the customer and the manufacturer through shared maintenance responsibilities.
4. While the focus in this article has been on product warranties, the models

and methods presented are equally applicable to service warranties. Like products, service warranties are binding commitments by providers to ensure acceptable quality of their service for some prescribed period of time following delivery. With growing customer demands for more reliable and higher quality products and services, service warranties are likely to receive much greater attention in the future. Quantitative methods are needed for examining economic decisions for this class of warranties. The issues are essentially the same, that is, the cost, length of warranty coverage, compensation, and reserve funds. However, the analogy to failure characteristics is less likely to apply. There is need for a framework for service warranty models.

NOTATION

FRW	Free replacement warranty policy
IFR	Increasing failure rate
PM	Preventive maintenance
PRW	Prorata replacement warranty policy
$B(w)$	Expected cost-benefit function over $(0, w)$
b_0, b_1	Parameters for warranty benefit function
c, c_1	Unit warranty cost to the manufacturer
c_s, c_d, c_r, c_{PM}	Unit costs for replacement, downtime, repair, and PM
$C(w, \phi)$	Expected warranty cost to the manufacturer
$CR(\tau)$	Long-run expected cost rate
δ	Discount factor
β, θ	Weibull distribution parameters: slope and characteristic value
$F(t), f(t)$	Probability distribution and density functions for failure time T
$\bar{F}(t)$	$= 1 - F(t)$, survivor function
λ	Parameter for exponential distribution

$M(t), m(t)$	Renewal function and renewal density function
μ	Mean product lifetime
$N(t)$	Number of failures in $(0, t]$
P	Rate of return
π	Price change per period
$r(t)$	$= f(t)/\bar{F}(t)$, failure rate function
$R(w)$	Reserve resources for warranty of length $w > 0$
T	Non-negative failure time random variable
τ	Replacement time
$X_i(t)$	Unit warranty cost of failure i
$X_D(t)$	Unit warranty cost with discounting

ENDNOTE

WHY RISK IS NOT VARIANCE

LOUIS ANTHONY COX, JR.

Sciences, University of Colorado,
Denver, Colorado

WILLIAM A. HUBER
Quantitative Decisions, Rosemont,
Pennsylvania

FRAMEWORK AND RESULTS

The following two plausible principles for managing financial investment risks are mutually inconsistent, in general

1. *Rule 1: Make Dominating Choices.* Other things being held equal, given a choice between a smaller probability of gain and a larger probability of gain, a decision maker should always choose the larger probability of gain. For example, given a choice between winning \$100 with probability 0.1 and winning \$100 with probability 0.2, rational decision makers who prefer more dollars to less should choose the option that gives a 0.2 probability of winning the \$100.
2. *Rule 2: Seek Mean–Variance Efficiency (Higher Variance Requires Higher Mean Return).* Given a choice among risky prospects, an investor should require more expected return to accept a prospect with more variance than to accept a prospect with less variance. For example, a 0.2 chance of winning \$100 (else nothing) has a higher variance than a 0.1 chance of winning \$100, but it also has a higher mean.

Rule 1 is implied by the decision-analytic principle of first-order stochastic dominance [1]: Prospects that give higher probabilities of preferred outcomes (and lower probabilities of less preferred outcomes) should be

preferred. Rule 2 provides the basis for many current efficient portfolio and mathematical optimization (e.g., quadratic programming) approaches to optimal investment (http://en.wikipedia.org/wiki/Modern_portfolio_theor). Although theorists have noted that some risk-averse decision makers may prefer some mean-preserving increases in variance (*ibid*), the idea that volatility in returns, as measured by variance or standard deviation, is generally undesirable to risk-averse investors, and that it should be avoided or compensated by higher expected returns, is still widely taught and practiced. However, *Rules 1 and 2 are incompatible*, in general, as demonstrated next. We introduce this incompatibility by first assuming that decision makers have indifference curves for mean–variance combinations, and then discuss why it holds even if no indifference curves exist.

Following the literature on mean–variance decision making, suppose that a decision maker has positively sloped continuous indifference curves in mean–variance space [2]. To any mean–variance pair (m, v) (a point in the mean–variance space), there corresponds a *certainty equivalent*, namely the point at which the indifference curve through (m, v) reaches the horizontal (mean) axis. The indifference curve through the origin $(0, 0)$ separates *acceptable risks* (those with positive certainty equivalents, lying below and to the right of the curve, if return is desirable) from *unacceptable risks* (those with negative certainty equivalents, lying above and to the left of it). To make an unacceptable risk acceptable in this framework, one must increase its mean return or reduce its variance.

The following result holds if we assume that there is at least one mean–variance combination (m, v) that the decision maker considers to be unacceptable (i.e., above the indifference curve through the origin, if such indifference curves exist).

Theorem. *If a decision maker considers all prospects corresponding to a particular mean–variance pair (m, v) to be*

unacceptable, then the decision maker considers unacceptable some prospects with positive expected values and no possibility of loss.

Proof. Huber [3] notes that one can construct explicit return distributions (e.g., with log-normally distributed returns) that have any specified positive (m, v) parameter values, but that have positive support, and hence no possibility of loss.

Such a decision maker prefers the *status quo* or “nothing ventured, nothing gained” point $(0, 0)$ to the possibility of winning a positive amount without any possibility of a loss, violating Rule 1. In this sense, Rules 1 and 2 are incompatible.

This incompatibility result does not require that a decision maker have well-defined indifference curves for mean–variance combinations, even though this is a common assumption in mean–variance risk models. Instead, the theorem only requires that there be at least one mean–variance combination, the (m, v) pair in the statement of the theorem, that the decision maker finds unacceptable.

Older, less general, results make a similar point by noting conditions under which binomial lotteries (yielding a known positive return with probability p , else nothing) can be used to construct parabolas in mean variance space, as p ranges from 0 to 1 (with $v = 0$ at both end points and rising to a maximum at $p = 0.5$) that intersect upward-sloping indifference curves twice, once for the ascending (positively sloped) portion of the parabola and once for its descending (negatively sloped) portion [4]. In any such construction, the rightmost intersection represents a stochastically dominant prospect (higher success probability p , which should be preferred, by Rule 1) compared to the leftmost intersection. That both points lie on the same indifference curve violates Rule 1.

DISCUSSION

Students of finance are often taught that “risk” is measured by the variance or

standard deviation of returns around an expected value. On the other hand, students of health, safety, and environmental (HS&E) and reliability engineering risk analysis are often taught that “risk” is determined by the probabilities of different consequences. Simple constructions show why the second approach (considering different specific consequences and their probabilities) can be preferable to considering only means and variances.

The finding that variance is problematic as a measure of risk is not new. The most common critique in the theoretical decision analysis and financial economics literature is that mean–variance analysis is compatible with von Neumann–Morgenstern expected utility theory only under very restrictive conditions (e.g., if all risky prospects have normal or location-scale distributions and utility functions are quadratic, implying that less money is preferred to more, for some amounts) [5,6]. Mean–variance dominance and stochastic dominance relations for location-scale distributions do not coincide in general [2]. Indeed, expected utility theory is inconsistent with all possible moment-based preference models (in which preferences are determined by mean, variance, skewness, kurtosis, etc.) for many utility functions [7]. Variance is also inconsistent with proposed normative axioms for coherent financial risk measures (nonnegativity, homogeneity, and subadditivity, which together imply that deterministic outcomes have zero risk; and shift-invariance, which implies that adding a constant to a random variable does not change its risk) [8]. Empirical studies since the 1960s have demonstrated that real decision makers pay attention to more than mean and variance in their choices among risky prospects [9], sparking a search for alternative measures of risk that would be consistent with stochastic dominance under usefully general conditions [10–14].

Thus, the above theorem is consistent with a long line of research. However, this recent version demonstrates a conflict between Rules 1 and 2, making only minimal assumptions (in particular, not requiring the framework of von Neumann–Morgenstern

expected utility theory or other sets of normative axioms for risk measures) and using only elementary mathematics. It may therefore be useful in illustrating why knowing the variances and expected returns from alternative investment choices (or other actions) does not necessarily suffice to identify the choice with the most desirable probability distribution of consequences.

WHY TRADITIONAL KANBAN CALCULATIONS FAIL IN VOLATILE ENVIRONMENTS

COLIN KESSINGER
ALLAN GRAY
End-to-End Analytics,
Palo Alto, California

INTRODUCTION

The goal of this article is to familiarize the reader with some of the tools, techniques, and processes commonly associated with the implementation of kanbans or reorder points (ROPs), and to discuss some common pitfalls when lead times are long and demand is volatile and/or seasonal.

The use of kanbans is closely associated with the Toyota Production System and Lean Manufacturing. Without recounting the entire history of the kanban concept, it is important to recognize several aspects of the environment in which it was developed. In particular, kanbans served as the primary mechanism for pulling material between manufacturing stages in factories, where the master production schedule was fixed with minimal variation, and where the lead times between stages were measured in minutes or hours instead of weeks. Additionally, the primary purpose of kanbans was to govern a smooth flow through the factory and manage process variability.

In this environment, there was little or no need to statistically size the kanbans. The process was driven by a continuous improvement cycle in which Toyota reduced inventory levels each time it identified and eliminated a source of process variation. By design, there was no inventory within the factory to manage demand variability. Most of this variability was managed through the substantial finished goods inventory sitting on dealer lots.

In recent years, however, the kanban concept has been applied to govern replenishment not just between manufacturing cells in a single factory, but between factories, and between firms. We can see references to this both in the academic literature [1] and amongst practitioners who work in this space [2]. Indeed, in high-tech supply chains, possibly encouraged by the rise of the “Lean” movement, many managers appear to have abandoned the use of the term “reorder point” and now think exclusively in terms of kanbans.

This expansion of the scope of “kanban thinking” to cover the entire supply chain carries with it various hidden perils, because kanbans were developed in settings quite unlike many of the environments where kanbans are being implemented today. First, lead times are often much longer. Consider the typical high-tech supply chain which almost certainly includes a variety of semiconductors (processors, ASICs, FPGAs, passives, memory), power supplies, and LCDs, all of which can have lead times between 8 and 26 weeks. Second, demand volatility and variability are also considerably higher. For example, companies that manufacture consumer products face increasingly short product life cycles and are subject to seasonal demand peaks (back-to-school, Christmas, etc.) Companies that sell capital equipment or network infrastructure are also subject to these seasonal effects, but also see significant volatility within each quarter (“hockey-stick” effect) and the tremendous variability that generally accompanies “high mix, low volume” products.

To summarize, we have identified two key areas of difference between the preeminent implementation of kanbans and the environments that many of us encounter in our own supply chains. The key contrasts are shorter lead times and less variability/volatility versus longer lead times and higher demand volatility/variability. In recognition of these differences, companies have experimented with a variety of “fixes” to setting and managing kanban levels and, in our

experience, have consistently come up short. The remainder of the article will examine and address why this has been the case.

THE ORIGIN OF THE SHORTCOMINGS

There are three primary root-causes of the poor performance that we see. First and foremost, “out-of-the-box” implementations of the “standard” inventory formulas are a very poor fit for the environment in which we are interested. Second, the typical personnel responsible for analyzing the data and implementing and managing inventory programs do not have the necessary training to do so. Third, very few companies have designed a solution where they look at their entire supply chain as a system of *flows* rather than a sequence of isolated *piles* of inventory. In this paper we will focus on the first of these three shortcomings, but in no way are we suggesting that the other two are less important.

The first question that we should ask ourselves is why the standard formulas do not work. The academic community has been researching inventory theory for over 90 years and yet only a small fraction of their findings have made it into practice. We can attribute this to two factors. First, the majority of academic research tends to focus on stylized models meant to generate managerial insight. From this research, we can quantify the impact of long lead times and demand variability, and we learned about the benefits of risk-pooling and postponement, all of which are significant contributions. However, much of this research makes a series of strong assumptions which greatly facilitate our ability to extract these insights, but undermine efforts to use it in real-world situations.

The strongest of these assumptions is that the key parameters are “stationary”. In layman’s terms, this means that the parameters are constant. For demand, this implies that the run-rate (average) and the variability (standard deviation) remain constant over time. This also implies that the key cost variables remain constant over time. In such a world, forecasting is irrelevant and it is fairly straightforward to compute the

average and standard deviation of historical demand and apply the classic “Newsvendor” inventory formula. The textbook by Nahmias [3], *Production and Operations Analysis*, provides an excellent practical introduction to the Newsvendor Model and a list of useful references for readers who would like to explore more advanced models.

Unfortunately, whether working with baked goods, premium cosmetics, PC’s, routers, capital equipment, or bottled water, we simply have not found stationarity to be a very good assumption.

Aware of this deficiency, academics have responded by developing a substantial body of nonstationary models. Without providing a comprehensive review of this work, but pointing to several good examples, we can see that this work started as far back in 1962 with Iglehart and Karlin [4] looking at nonstationary demand, remained a topic of ongoing interest in the 90s with Song and Zipkin [5] looking at fluctuating demand patterns, and in the 2000s with Dong and Lee [6] examining time-correlated demand (with the added bonus of doing this in a multi-echelon setting). However, as Gavirneni and Tayur [7] note, these models “are either very complex and computationally expensive or specific to the setting they address and not easily generalized”. Despite their efforts to overcome these obstacles, the average practitioner would still find their methodology quite daunting and the research since their publication in 1993 has not overcome these obstacles. As a result, companies have to make a number of adaptations in their methodologies and processes in order to apply any kind of scientific inventory management. In the remainder of this article we will review many of the issues associated with these efforts.

CHOOSING THE RIGHT DEMAND SIGNAL TO DRIVE KANBANS

Any inventory improvement initiative should start with a characterization and quantification of demand and the uncertainty associated with it. After all, the primary role of inventory is to address this uncertainty.

This issue quickly becomes cloudy when implementing kanbans since there is considerable debate as to whether the model should be consumption-driven or forecast-driven. Purists often argue that kanbans are “pull” models and should be driven by consumption. We would argue that the execution (replenishment triggers) of the pull models should be driven by consumption but that the planning (kanban parameter setting) may need to be driven by forecasts. In either case, most companies have implemented both methodologies inadequately.

Consumption-Based ROP Calculations

The majority of textbook inventory models require the computation of a mean (or average) and standard deviation of demand over the lead time. The typical approach is to choose some standard period length (typically days or weeks), calculate the mean and standard deviation of demand of these observations and then scale by the square root of the lead time to calculate the standard deviation over the lead time. As simple as this sounds, and as much as this is encouraged by standard textbooks, there are at least five different possibilities to make significant mistakes.

Many companies start off on the wrong foot when they choose the historical horizon for analysis. In many cases, the horizon is too short, and therefore the calculations are very noisy and the fit is poor. In other cases, the horizon is too long and the standard deviation captures product life-cycle effects rather than the short-term variability. The challenge here is that the analysis horizon has to be several multiples of the lead time. However, we must also test whether the demand pattern has significantly shifted during that time period due to product life-cycle, cyclical, or other explainable factors. With long lead time items, you may often find yourself in a situation where there is no horizon that satisfies both constraints.

Companies often make a series of errors when computing the standard deviation over the lead time. Most companies started with the textbook implementation which prescribes the scaling by the square root of the lead time as described above. However,

that formula makes two strong assumptions: demand parameters do not change over time, and demand between periods is independent. For example, when looking at daily increments, you may run into trouble if you have a significant number of customers that only order on specific days. Similarly, when looking at weekly increments, you may find numerous examples where the production schedule called for 100 units for two consecutive weeks, and where you consistently produced 200 units in consecutive two-week periods, but where you did not actually produce 100 units in any given week. As a way of benchmarking your own progress, many companies have already identified this issue and pursued other methods for calculating the standard deviation of demand over the lead time.

As an alternative, some companies compute the standard deviation of lead time directly. Consider the case where your lead time is 43 days. Starting with daily data, you define each observation of lead time demand as sum of demand over the previous (or future) 43 days and then calculate the standard deviation of these observations. The good news is that this method eliminates the issues associated with the previous calculation. The bad news is that it does NOT solve the horizon (amount of data required) problem. You can see this in the following example.

Assume again that the lead time is 43 days and that you have 60 days of shipment history. How many data points do you have? One calculation would suggest that you have 17 observations: points 1 to 43, 2 to 44, 3 to 45, ..., 17 to 60. However, each of these observations has 42 points in common with each successor and predecessor, and all 17 points have at least 26 points in common. Therefore, each of the data points is highly correlated. As a result, when computing the standard deviation, you often (but not always) will dramatically underestimate the true standard deviation of the process. If you have considerable history (several multiples of the lead time) then this problem disappears. But we have already established that needing a long history is a problem in its own right.

Figure 1. Example of a consumption-based ROP performing poorly in the face of ramping/declining demand.

Modified Consumption-Based ROPs

In some cases, companies acknowledged that they need a long horizon to estimate the standard deviation, but used a shorter horizon to determine the average run-rate in their kanban calculation. The motivation here stems from the notion that more recent demand is a better proxy for the upcoming demand. This approach is simply invalid. Mathematically there is no justification to use an average from one calculation and the standard deviation from another. To understand this, consider the definition of the variance (the square of the standard deviation): it is the average of the squared distances from the mean (average) and thus is a function of that mean. However, in this case, the mean of the longer horizon has been deemed invalid. Thus, if you are not satisfied with the average associated with the older data, then you cannot be satisfied with the standard deviation from that same older data.

The following example illustrates several of the issues that we see with consumption-based ROP calculations. The example shows a product with a six-week lead time that consistently ramped up for an extended period and is beginning a period of decline (Fig. 1). If shown, the company's forecast for this item would show an expected ongoing decline in volume.

As discussed above, we are interested in the demand over the lead time (labeled as lead time demand) and is the sum of weekly demand over the lead time looking forward. The ROP has been calculated using mean and

standard deviation parameters calculated on 26 weeks of history. A direct comparison of the ROP and the lead time demand gives us a visual assessment of how well the ROP would perform. If the lead time demand is higher than the ROP, then stockouts will result; if the ROP is much higher than the lead time demand, there will be excess inventory.

This example highlights three critical points. First, the consumption-based model will never catch up to ramping volumes. Second, as soon as the ramp becomes a decline, the consumption-based model will overshoot actual consumption severely. While we have shown an example with only six-week lead times, a significant portion of the typical high-tech supply chain has lead times in excess of 14 weeks. With a 14-week lead time and a 26-week horizon, it will take 2+ quarters for this problem to work itself out. Third, the company knew this was a ramping product and the consumption-based model pays the price for not using that knowledge. We see very similar behavior whenever there is explainable variability in demand: for example, within-quarter hockey-stick effects, seasonality, price changes, or product life cycles. Figure 2 shows another example without this ramp effect, but still clear cases where the reactive nature of this consumption-based ROP methodology systemically moves in the opposite direction of demand.

In summary, consumption-based ROP models face almost insurmountable challenges when applied to high-variability,

Figure 2. Example of a consumption-based ROP performing poorly even without a sustained upward or downward trend in demand.

high-volatility demand patterns, particularly as lead times grow. Too much history and your parameters no longer reflect the current reality (in the above example, history becomes irrelevant quite quickly); too little history and your critical model assumptions break down. Combine this with the fact that the methodology does not work for any new products, and you come to the conclusion that this approach has little to offer.

Before we turn our attention to using a forecast-based ROP calculation, we leave with you two last related questions. If you decide that a simple model based on historical consumption is the best predictor of future material requirements, then why have sales, marketing, and management generate forecasts? Conversely, if you have a forecasting process and it is proven to add value, then why would you choose a less predictive method (pure consumption) to drive the most critical components in your supply chain?

Partially Forecast-Based ROP Calculations

As suggested above, many companies quickly realized that a pure consumption-based ROP calculation did not respond quickly enough to changing demand situations. As such, they have experimented with a variety of efforts to incorporate forecasts into their ROP calculations.

We will start this discussion by looking at consumption-based ROPs as one class of forecast-based ROP calculation. To understand this connection, recognize that

the average and the standard deviation of historical consumption are only forecasts of the average and standard deviation of future demand. In fact, driving your ROP based on consumption is equivalent to using a moving average forecast with the moving average parameter equal to the amount of history used in the calculation (Not surprisingly, this typically is a poor forecast, but that is the subject of another paper.)

This raises the final objection to the standard practice used in estimating the standard deviation in consumption-based ROP calculations. Given that the consumption data provides only a forecast, the standard deviation should reflect the forecast error, not the demand volatility. In the example shown above (14-week lead time product) the standard deviation over the preceding 26 weeks was 2801. However, if you took the historical run-rate over the preceding 26 weeks as the forecast and measured the standard deviation of the forecast error, the resulting standard deviation is 3911, more than 30% higher. Moreover, if the business forecast (purple line) proves to be at all accurate and volume declines, the standard deviation based on historical consumption will decrease, but the forecast error associated with the consumption-based run-rate will increase. This dynamic will only worsen the performance of the consumption-based ROP.

Turning our attention to ROP calculations that explicitly use forecasts, we commonly see another set of mistakes. Similar to the above discussion, the problem originates

from efforts to set the cycle stock using the forecast, and the safety stock using historical consumption. We refer to this as the Partially Forecast-Based ROP calculation because it still uses consumption-based data to calculate the standard deviation. This fails the same test as the consumption-based ROP calculation that used one horizon to calculate the standard deviation and another to determine the average run-rate. In this case, the standard deviation is measured as the distance from an average based on a historical consumption rate which may have no functional relationship to the forecast, and which in many cases may be wildly different. Putting aside the theory, clearly, it makes little sense to take the standard deviation of the historical data if the historical average is two times or one half of the current forecast—and yet many companies do just that. It is also worth noting that this methodology fails for new product introductions because of its reliance on there being sufficient history to calculate the standard deviation.

Finally, some companies have attempted hybrid approaches in which the historical run-rate, the historical standard deviation, or both are scaled based on the difference between the historical average and the forecast. Specifically, we have seen companies take a weighted average of the historical run-rate and the forecast. Given that this results in another forecast, by our arguments above, there is no basis to use the historically generated standard deviation. By the same argument this also eliminates any effort to scale the standard deviation. Once again this should also fail the common sense test. Typically, as volume increases, forecast error (measured as a percentage) decreases in a nonlinear fashion. So again, while these approaches may feel intuitive, the culmination of all of these mistakes should leave the decision maker with no confidence that they have the “right” inventory levels, or even that they have (not?) consistently overstated or understated the inventory levels. In fact, the company is probably better served using an “unscientific” method than using any of the above methodologies.

SETTING SERVICE LEVELS

The task of determining the optimal target service level is both theoretically and practically challenging. In fact, the topic is sufficiently complex that it is more appropriate for a more advanced text. However, there are two common pitfalls that the practitioner should avoid when selecting the service levels.

One of the most common mistakes is targeting the same service level for all products, customers, or segments. The process of selecting service levels should begin with the specification of the business requirements. This entails determining the response time and service level requirements for each customer/market segment. As we would expect, not all customers, segments, or markets will have the same response time or service level requirements. Similarly, different products will have varying profit margins, lead times, and inventory carrying costs (physical storage, depreciation, risk of obsolescence, etc.). As such, it should be obvious that each of these categories should have a different service level.

Another common set of mistakes occur when companies convert target service levels into “z-scores” for the normal distribution. Putting aside that the demand variability and forecast error often are not normal, a more fundamental problem results from the confusion between two types of service level: “type 1”, which is what the academic literature refers to as service level, and “type 2”, which is also referred to as the fill rate. The type 1 service level measures the probability of satisfying 100% of the orders on time, whereas the type 2 fill-rates measure the percent of orders satisfied on time. The chart below shows how these measures differ (Fig. 3).

Some of the confusion can be traced from poor translation of the academic models into practice. It turns out that in the “Newsvendor” model (one of the best-known results in inventory theory), the optimal solution specifies the type 1 service level based purely on the economics of the situation. However, in practice, most companies cannot specify the

Figure 3. Distinction between Type I and Type II service levels.

necessary parameters to apply the Newsvendor formula. Instead, they (often appropriately) make an assessment of the optimal service level based on the criteria discussed, but they actually specify the type 2 fill-rate target rather than the type 1 service level. In fact, we have never met a manager who expressed any objective resembling the probability of a stock-out as a desired target. Nonetheless, each and every time the manager expressed their target service level, it was treated as a type 1 service level metric in the derivation of the z-score. As you can see from above, this almost certainly results in driving inventory levels that are much too high.

CLOSING REMARKS

In this article, we have focused on the pitfalls of trying to implement standard statistical inventory sizing techniques in environments with long lead times and elevated levels of demand volatility that result from seasonal patterns or short product life-cycles. The standard textbook formula only has three to five parameters (depending on the form of the model) and yet there are numerous opportunities to get each of them wrong. Remarkably, this is true even though we limited our discussion to the simplest of all settings: a single, stand-alone item with inventory being held in one location at one level in the supply chain.

Of course many, if not most, real-world kanban or ROP implementations face additional complexity, such as multiple items in a Bill-of-Material relationship, or

multiple inventory locations, or multiple levels ("echelons") in the supply chain. As with the single-item, single-location setting, many of the common practices and rules-of-thumb that are used to deal with this added complexity seem intuitive—and yet are fundamentally incorrect. For example, this is true of most "ABC" policies, and of the practice of multiplying service levels in assemble-to-order environments to approximate the ship-set end-product service level.

Faced with so many pitfalls, it is reasonable to ask whether there is any "right" way to statistically size inventory levels, and if there is, whether it is so complicated as to be not worth the effort required. The good news is that the right answer is usually not particularly complicated. The bad news is that the right answer is different in most situations. Nonetheless, some useful general principles are as follows:

- Make the best forecast you can and use it, unless the lead time is very short and demand variability is very low.
- Measure cumulative forecast error over lead time (rather than measuring only the one-period ahead forecast error and multiplying by the square root of the lead time).
- Where there is not enough history to measure this well, reference "similar" items with more history.
- Consider using a simulation-based approach with the real demand and forecast data to find optimal inventory settings.

- Monitor forecasts and stockouts/inventory levels to detect cases where the forecast model and/or ROP model may no longer appropriate because of some change in demand behavior.

Just as we see in effective implementations of statistical forecasting techniques, the right solution requires a combination of analytical rigor (to consistently set the appropriate inventory levels) and effective exception management (to quickly and systematically identify the inevitable misses that any analytical solution will have from time to time). If this article has equipped you with an awareness of the most common pitfalls in the former, and the consequent need for the latter, then you are well on your way toward implementing an effective kanban or ROP mechanism.

WRITING ORMS/ANALYTICS CASES

MEHMET A. BEGEN
SRINIVAS KRISHNAMOORTHY
and JOHN WILSON

Richard Ivey School of
Business, London, Ontario,
Canada

INTRODUCTION

Many of us have experienced the situation where students who are adept at the technical aspects of management science, statistics, or mathematics are unable to apply these methods in real-world situations. This can be the case even for students who have achieved the highest scores in their quantitative classes. We certainly have found this to be the case in our first-year MBA and HBA (honors in business administration) classes: prior success in quantitative methods is not necessarily a good indicator of adeptness in our beginning case-based classes. It is distressing to see students with good quantitative skills unable to parley this into management advantage. The case method helps with resolving this issue.

A primary goal of the case-based method is to simulate situations that a manager would experience. By learning through cases, students become more proficient in applying quantitative methods in a practical setting. In addition, there are other benefits. Students learn important presentation, writing, and discussion skills. Presentation of results is as important (or even more important) than being able to derive the results. After all, what use is a superb management science analysis if no one can be convinced of its merits or understand the managerial ramifications, strengths, or weaknesses? The case method requires that students develop the necessary verbal skills to identify and discuss managerial issues and then identify and implement appropriate quantitative

methodologies. Harvard, Ivey, and Darden are business schools that are most prominent in their use of the case method. A number of other schools have begun to use it as well. The method can be used in a wide variety of ways, for example, pure case teaching (in which there is a case in each class) or a hybrid teaching (a combination of cases and lectures).

This article provides a reference for instructors who wish to write cases. There are many reasons why an instructor may want to write a case. It is easier for an instructor to teach a self-written case rather than the one written by someone else. Writing a case compels the instructor to think hard about what and how he or she wants to teach in the course. By writing a case, an instructor can fulfill the need to find suitable cases for his or her teaching objectives. Teaching customized material and being the author of cases can greatly increase an instructor's credibility with students and enhance the learning process. In fact, students often want to be involved with case writing as they see it as a good training experience and feel that they are "leaving their mark" in the school. Sometimes, writing a case can create ideas for research. In addition, there are publication outlets for cases and innovative teaching. Often, for the purposes of examinations and assignments, an instructor looks for cases that students have not encountered before. The best way to find a case that is not widely available in the public arena is write a new one. Writing a case allows an instructor to customize the case (in terms of difficulty level, topic, industry, data, and operations research and management science (ORMS) concepts) for the examination.

There are a wide variety of cases available for the purposes of meeting different learning objectives. In addition, there are various approaches and philosophies when it comes to writing cases. Typically, cases are structured according to the following model: a background description of the company and industry; a description of the decision problem facing the manager;

related background information; and tables, graphs, and other data that could relate to the decision. It is important to be comprehensive in supplying material that might aid the decision-maker. Often, extraneous information will be included. This is in order to mimic the real world where one has to sift through the data to identify the right information. Students (and sometimes instructors) may find this frustrating but it is necessary as it reflects reality and helps them develop the skills necessary to identify information relevant to the decision at hand.

We feel that it is important to realize that there is not a “one-size-fits-all” approach to case writing. Flexibility in approaching case writing leads to a more varied and enjoyable experience. In this article, we share some of our experiences in the hope that these might be helpful to others. We certainly do not intend to be prescriptive. However, we feel that there are some common approaches and guidelines that can be of assistance. We will illustrate some points with cases that we commonly use. Sections on types of cases and publishing cases are included as these can be helpful resources for someone contemplating case writing. We feel that a teaching note is part and parcel of any case and include a section on this as well.

We believe that this article will be useful for teaching in business schools as well as industrial engineering and operations research departments. Even though engineering faculty spend more time on theoretical concepts in their courses as opposed to business faculty who focus on the managerial implications of a concept, cases can still be written and used by either faculty.

LITERATURE REVIEW

A number of authors have shared their ideas on writing cases. Linder [1] describes his ideas for writing cases using a timeline that includes preparation, interviewing, draft, quote approval, case review, and sign off. An exhaustive resource for case writing principles is available online at the National Institute for Case Teaching in Science [2]. Abel [3] provides an elegant description of the principles for a well-written case. A complete

guide to the case writing process is provided by Leenders *et al.* [4]. More recently, Lane [5] discusses the activities in organizing and presenting information in the case format. In similar vein, Roberts [6] describes the process of writing business cases. His article offers guidelines for identifying a good case, the process of working in the field with the company, and, finally, techniques for writing a good case. Drake [7] presents a compelling argument for writing and using cases. For a review of articles that deal with the case method of teaching, see Begen *et al.* [8]. These articles can certainly be useful for those contemplating writing a case.

IDEAS FOR WRITING CASES

Some instructors are intimidated by the idea of writing a case because they believe that it has to be inspired by a real-world consulting project that resulted in an Interfaces’ article or Institute for operations research and management sciences (INFORMS) Edelman Prize finalists’ presentation. Of course, real projects undertaken by the instructor are great sources for cases but ideas can also come from a variety of other sources as well. In our experience, business contacts and students are a great source of ideas. Many of our students undertake field projects for clients as part of their course requirements. We often use student internships or consulting projects to find a real-world problem and develop as cases. This was certainly the way the idea for the *Deloitte Recommends Client Selection to Regency Bank* [9] case was born. Executive MBA students are adept at basing their case ideas on their current jobs. One can also use industry contacts to identify business issues/challenges and obtain data in order to develop and write a case. *Seoul National Bank: The Chief Credit Officer’s Dilemma* [10] is an example of a case that was written using such an approach.

Cases can be fictional as well. Ideas for fictional cases are a product of the author’s imagination. The spark for the idea may come from reading an article in a newspaper or magazine or even having a conversation with a colleague. *SIGA Technologies: Profit-ing From Uncertainty* [11] was written based

on a newspaper finance article. Sometimes, the writer's research may motivate fictitious or real-world cases that capture management insights from the research. (*Kimpton Hotels* [12] and *The Clonlara Hotel* [13] are exemplars.) Whatever the source of ideas, it is important that the case follows a basic structure.

TYPES OF CASE

Cases can be used to introduce specific quantitative topics in a manner that has students immediately see the applicability of the techniques. It can help to provide a series of straightforward questions that will focus students' attention on the relevant issues and lead them toward a more complex analysis. This approach can be seen, for instance, in *Superior Grain* [14] where students are asked to fill out a worksheet to develop some important preliminary insights. The case *Buckeye* [15] is a product mix selection case. Appendices to the case contain a consultant's report and an outline of linear programming (LP) approaches. Here, students realize that LP is the most appropriate technique for the problem but they are given no help in setting up the analysis. Instead, a description of the problem and associated constraints is provided in a nontechnical matter that would closely resemble the information that managers would receive. For these cases, we sometimes would include a "mini-lecture" on some of the more technical aspects.

Cases that are written as a consultant's report can provide for lively discussion. Here, the format is similar to the classical case: company/industry description, information on the decision and possible data, and so on. However, a consultant's report is included. Here, the manager is in the situation of receiving a consultant's report and trying to understand, evaluate, and, possibly, implement the recommendations. One case along these lines is *Lansink* [16]. It is important to write the case in as neutral a manner as possible so that the students are not prejudiced to approach the consultant's report either negatively or positively. This situation of receiving a consultant's report and trying to

digest and evaluate is something that most managers will experience.

"Capstone" cases are comprehensive cases that require students to utilize many techniques. Students find these cases not only extraordinarily difficult but also most rewarding. We often have students tackle such cases in teams so that all students, no matter what their strongest skills might be, can contribute. A good example of such a case is *Enron* [17].

A case such as *Cells for Life* [18] follows a completely different tack. No data is supplied in the *A-case*. Instead, students are asked to put themselves in the positions of consultants who have been brought into help with decision-making. As such, they are to ask questions and request data that will help in making the decision. Our experience with this case has been very illuminating: for the *A-case*, no analysis is required. Indeed, no mathematical skills whatsoever are required at this stage of the analysis. Yet, most students—both those who are mathematically adept and those who claim to have no mathematical skills—seem to find this assignment remarkably difficult. Once a discussion on these issues has concluded, we then supply the students with data they requested and extra data that might be useful and ask them to prepare a consultant's report. We have used this case both at the beginning of our course to introduce the idea of the case-based method and near the end to have students tested on how their skills have evolved.

Cases are like stories: they can be real or fictional. When based on an actual company, the names and data may be frequently disguised for confidentiality purposes. When based on public events, for instance, the US presidential election or the World Series Baseball, there is rarely a requirement to disguise data although imaginary characters may be introduced to add a storytelling element to the case. Fictional cases are based on characters, situations, and data created by the author and are often sometimes to as "armchair" cases. Cases based on an actual company require the company's commitment to share information. Often requiring site visits and meetings with management, writing

a real company case is an exposure to the practicalities of real business situations. The company must “sign off” on the final version of the case, giving the author the right to publish the case and use it in a classroom or examination setting. (For instances, where the data is sensitive, a company’s consent to publish can often be obtained by an effort to disguise the data, e.g., via randomization.) Real cases are usually more difficult and challenging to write but they are believed to have more teaching and learning benefits, see Bell and von Lanzener [19].

There are also technical notes that are not really cases but are written to describe a certain topic, for example, logistic regression [20] solver in Excel and VBA [21], cost-effectiveness analysis [22], and introducing software [23]. These are meant to be assigned as customized readings and supplementary materials for students.

WRITING CASES

The case writer should have clear objective(s) in writing a case. For example, it could be to illustrate the use of a technique or techniques (e.g., LP, statistical analysis, simulation, or a combination of these concepts), to introduce a new business/opportunity (e.g., a new type of web-based auction), or to teach an ORMS concept (e.g., revenue management) or a blend of these. The difficulty level should also be properly adjusted for the desired learning purposes. For example, certain cases may provide alternative decisions and ask readers to evaluate each one of them and choose among them, whereas some other cases do not reveal alternatives or even give a hint about the decision(s) but just introduce issues. The data itself can provide difficulties: some of the facts/data provided in the case may or may not be relevant for the issue(s) and readers may need to make some sensible assumptions to see which ones matter. Perhaps, some required data is not provided and the reader evaluates alternatives for a range of inputs to see how decisions might change. Sometimes, cases are meant as introductions to certain techniques. For instance, suppose, as an instructor you are teaching optimization for the first time with cases. You may

want to start with an easy case: specifically, a case with simple LP where the body of the case provides hints about decision variables, objectives, and constraints so that readers can build their first optimization model. The next cases may require the use of a more advanced LP model (with no hints), binary variables, or non-LP. Before writing a case, the case writer has to consider the difficulty level that he or she is targeting.

A case is typically written with the following structure:

Introduction

The first paragraph of the case introduces the main character and the business problem. Some writers regard this as the most important part of the case. It entices the student to read the rest of the case. Readers are often won or lost in the introduction.

Cases should attract the interest of students by the first/opening paragraph if not by its title. Current cases usually get more attention than old ones. Real and famous companies (especially in the title) attract more interest. Cases should have a hook that sparks the curiosity of the reader after the opening paragraph.

Body

The body of the case provides further details of the business problem. Some secondary characters may be introduced as well. There are varying opinions among case writers about including extraneous material. Some believe that a more comprehensive view (even if it includes much material not immediately relevant to the problem at hand) captures the messiness of real business situations. Others feel that, while it is essential to provide the reader with the facts surrounding the business problem, care has to be taken to prune unnecessary details.

Background information is important in that it sets the problem in the broader framework of the business world and engages students on general issues beyond the quantitative methods they will eventually employ. It provides context and support for requiring an understanding of quantitative approaches. The material need not be

particularly relevant for the issue at hand as long as it enables the student to see this problem in the wider context of a general business situation. It can be helpful to personalize the issue, for example, phrases such as “Sally had a deadline for making recommendations on. . .” The goal here is to write enough so that student can envision being in the decision-maker’s shoes. The inclusion of relevant newspaper articles or company advertising material can add to a sense of comprehensiveness.

Like Aggarwal and Khera [24], we personally prefer shorter cases written in plain language. We find this to be most effective for analytics cases given the extra complications that quantitative analyses bring to cases. However, there are some case writers who have a different opinion. They prefer to write longer cases by including extra facts. For instance, Harvard cases are usually written in great detail.

Conclusion

The final paragraph reiterates the task faced by the main character. Any deadline for the completion of the task has to be emphasized here to capture the urgency of the situation.

Exhibits

The exhibits provide data that may help with the analysis. Care has to be taken to provide data in an authentic format—for instance, we have written cases in which some of the data items are missing. After all, data recording is an error-prone activity in corporations.

We feel it important that supporting data be as general as possible. It is rarely the case in the business world that one has only the data set that is relevant to the issue at hand. For instance, in a product mix problem, information on many products might be available. We often use *Red Brand Canners* [25] as an introduction to LP. This is a product mix case where the immediate decision for the decision-maker involves specific products. However, the information in the tables consists of information on many products. Also included is information on the overall and individual performance for various product lines. For the student, developing the

capability to find the right information from the plethora of available information is an important skill to learn and improve.

Cases allow students to solve real-world problems and involve them in decision-making process in a controlled laboratory-like environment. Cases should give enough background, facts, and information about the issue(s) but should not imply a solution method or provide any analysis, judgment, or prediction about the outcome. These are for readers to find and figure out themselves. Cases should not be easily “cracked”; the solution approach and answer should not be obvious but should be obtained after thoughtful analysis putting different pieces of the case together. Analysis and learning points should not be part of a case but the corresponding teaching note should have them. A case should be accompanied with a good teaching note. This increases its chances to be adopted and used by other instructors as well as forces the case writer to think thoroughly about the case, its objectives, solution approach, and its takeaways and make corrections and improvements before the case is finalized. For our cases, teaching notes are usually accompanied with (spreadsheet) models and data sets. PowerPoint slides and any video clips (e.g., of the company or process being studied) that illustrate the problem can be valuable additions.

To stimulate real-world decision-making, it is crucial to write cases that do not always lead to a single solution. Ideally, a case should lead students to identify multiple alternatives and figure out the trade-off of choosing one alternative over another. Of course, in some instances, a decision could be a yes-or-no type question but even in this situation, there can be different ways to formulate and reach an acceptable answer. A good case should allow students to identify minor and major issues and symptoms and enable them to discover their own methods/approaches to solve the case puzzle and come up with sound decisions and action plans.

It helps considerably to read and teach, see a few cases, and watch or learn about their use in classroom before attempting to write any. It is useful to read cases not only

in ORMS but also from other fields to have a broader understanding. Finally, reading cases from different publishers, authors, and books makes us more versatile case writers. For example, see Bodily [26], Liberatore and Nydick [27], Liang and Wang [28], Kim *et al.* [29], Currie [30], Long [31], and Cochran [32–36] for different use and type of cases.

Unlike many other subjects, ORMS cases usually have multiple aspects, for example, quantitative and qualitative, managerial, and data identification/extraction and analysis. (Depending on the case objectives, the case writer may give more or less emphasis to these topics, e.g., an introductory case on decision trees for business students and an advanced case on simulation for engineering students would be different in terms of technical difficulty, data, problem description, and teaching note.) Another difference is that there is usually more ambiguity, uncertainty, making sense of data, and obtaining information from it in ORMS cases. Furthermore, in order to teach a technical subject, cases difficulty levels vary more in ORMS. Writing case is a dynamic art. Often, a case will have to be revised based on the writer's experience using it in class. Students often provide unique perspectives that enrich the instructor's understanding of the business situation. By being flexible in our approach to case writing, we can enjoy this exercise of creating learning experiences for our students.

TEACHING NOTES

A teaching note is a valuable addition to the case. Indeed, we feel that a case is incomplete without an associated teaching note. A teaching note is typically written with the following structure:

Introduction

Here, the case is summarized by describing the main character and the business problem with a few details about the company.

Techniques and Concepts

A list of techniques and concepts covered helps the instructor fit the case in the course plan. An example of a list could be:

- decision analysis
- multiple regression analysis
- constructing confidence and prediction intervals
- simulation
- optimization.

Uses/Audience

Often, cases are written with a target audience in mind. By clearly defining the audience, we can ensure that the instructor chooses cases that match the expertise of his or her students. An example of a target audience would be undergraduate business students in a foundational analytics course.

Assignment Questions

Case discussions work if students spend time outside the classroom preparing for them. Assignment questions provide a framework for the preparation. It is important to keep the first couple of questions as open-ended as possible. Care has to be taken not to steer students to an “answer” or solution approach. One of the questions we like to use in our cases is what is the problem that Mr. XYZ is trying to solve or what is the decision that Ms. ABC has to make? Often, asking the students to provide a time line including when data is collected and decisions are made can help them understand the decision-making process a little better.

Suggested Teaching Plan

The teaching plan is meant to be a guideline for the instructor—not a script that the instructor should follow. A good plan will list suggestions for starting, directing, and concluding the discussion. The time to be spent in each phase should be provided as well. Once again, it has to be understood that the plan is not rigid—every instructor is going to have his or her own plan and style. Indeed, one should be wary of successful case teachers who insist that theirs is the

only way to proceed as in many cases it is their own idiosyncratic styles that successfully work for them. Others need to develop styles that work for them while, of course, observing and adapting the styles of others.

Solution Approach/Analysis

Providing a solution approach is necessary for the sake of completion. A spreadsheet file may also be provided to illustrate the modeling approach adopted. However, we recommend that the instructor solves the case on his or her own rather than mimicking the approach provided. In our experience, a case is best understood by solving it. In any case, there is rarely one correct way of solving a case.

Case Outcome

For real cases, it is useful to describe in the teaching note what actually happened in terms of the decision made and the business outcome. In our experience, memorable cases invariably arouse the interest of students with respect to the final outcome.

WRITING CASES FOR ENGINEERS

The biggest challenge that an instructor will face while writing and teaching cases for engineering students is that most engineers are used to the “teach me the tool, give me the problem, use the tool, and get the solution” approach. In reality, engineering problems in corporations are complex and ill-structured. There may not be one “solution” to the problem. We believe that the case writer should not succumb to the temptation to write a neatly packaged textbook case. Most engineering students become managers in corporations. It is imperative, therefore, that they learn to solve ill-structured problems.

We believe that engineering cases should be written in the same format and structure as business cases. Of course, the case writer may choose to include more technical details because engineering students are likely to have a stronger training in quantitative concepts as compared to business students. The case approach, however, is very useful in forcing them to realize that the communication

of their results is at least as important as the results themselves. However, the writing philosophy remains the same.

WRITING CASES IN OTHER BUSINESS DISCIPLINES

We find that cases written in other business disciplines such as marketing, strategy, and organizational behavior tend to be longer and more detailed. The data provided in the cases may be more at the strategic and structural levels, for example, industry structure, company financials, and company organizational charts. This is probably a legacy of the qualitative approaches used to tackle such cases. Students tend to spend more time reading the case and identifying key facts that may be used to make a decision. In ORMS cases, the data provided tends to be more at the tactical and operational levels, for example, demand and price schedules and processing time for a product. The students tend to spend less time reading the case and more time creating models and reaching conclusions based on the output of their model.

PUBLISHING CASES

Universities and business schools that use the case method in their teaching can sometimes be outlets for publishing cases. Often, such places will have a publishing arm devoted to cases. For example, the Harvard Business School [37], the Richard Ivey School of Business [38], Darden School of Business [39], Insead [40], and the Stanford Business School [41] accept cases from authors outside of their own faculty in addition to their own. There are also educational organizations such as the European Case Clearing House [42] that publish and distribute cases. Specialized journals such as *INFORMS Transactions on Education* [43] publish a variety of articles in the areas of ORMS teaching: cases, applications of spreadsheets, reviews, and opinion articles. The journal is available only in electronic format and allows open access of its articles to interested parties. Registered instructors can also obtain resources such as data sets, software, and spreadsheets.

The INFORMS annual case competition has resulted in the dissemination of several high quality cases. The competition was established in 2000 to promote the writing and use of cases in ORMS. The case competition web site [44] is another place to find cases. Entering this competition is a great way to get recognition for a case. (Cases submitted to the competition cannot have been published previously.)

The Journal of Business [45] is a peer-reviewed journal that provides high quality teaching and research cases in all major disciplines of management science. The Operations Management Education Review [46] publishes and sells peer-reviewed teaching cases. The Decision Science Journal of Innovative Education [47] publishes research pertaining to teaching and learning issues.

Textbooks on topics such as operations management, analytics [48], management science modeling, operations research, and quantitative decision-making are also sources for cases. Although publishing a case in a textbook is an option, unless you are authoring the textbook or know the author(s), it may not be the easiest way. Furthermore, most instructors who need cases usually find a suitable case for their needs at one of the university case-publishing web sites such as in Refs 37 and 38.

Certain academic centers, especially the ones doing projects with industry, may publish some of their projects as cases and make it available for academic use. Once such example is Centre for Operations Excellence (COE) in the Sauder School of Business at the University of British Columbia [49]. At the COE, master students are required to do a significant industry project for their degree and this is done with a team consisting of the student, technical analysts, faculty advisor, and a project manager. Projects are usually six months long and they can be thought as management consulting projects specializing in analytics and operations research. Some of these COE cases were successful in INFORMS case competitions [50, 51].

CONCLUSION

Using cases in ORMS/analytics teaching is not only effective but can also be fun and rewarding for both students and professors. One important reason for writing cases is simply the fact that case teachers need current and relevant cases. In addition, sometimes as a case teacher may need a specific case (e.g., a technique, industry, or decision type) and cannot find it elsewhere. In such a situation, he or she is motivated to write it him- or herself. (For instance, this was the case with *Clonlara* [13] and *Kimpton hotels* [12] where the authors needed cases in the relatively new area of Revenue Management.) New cases are often required for case examinations. Writing a case can be an excellent way to get started on a research project. For example, a student internship can turn into a case and continue as a research project. The cases one writes will be easier to teach. Teaching one's own case increases the instructor's credibility among students. An extra benefit of writing cases is that they help build a teaching portfolio (which can be important for career development). The cases can even be published in journals, books, or university publishing houses. There is also the possibility of participating in case competitions [24] by submitting a newly written case. Case writing can not only be enjoyable and rewarding but also expand one's teaching horizons.
